This article critically examines the existing methodologies including residue isolation and preconcentration, cleanup, chromatographic analysis, such as gas chromatography (GC), high-performance liquid chromatography (HPLC), hyphenated techniques, such as gas chromatography/mass spectrometry (GC/MS) and high-performance liquid chromatography/mass spectrometry (HPLC/MS), and some nonchromatographic techniques, such as immunoassay (IA), of herbicide residues in crops, food, and environmental samples. The main structural groups of herbicides discussed are imidazolinones (IMIs), aryloxyphenoxy propionic acids/esters, and diphenyl ethers (DPhEs).

1 INTRODUCTION

The development of chemicals in selective control of weed growth is a fascinating success story that has unfolded largely since the early 1980s. At present, herbicides represent the largest single agrochemical sector, worth approximately US$15 billion.

In order to limit environmental pollution and damage to humans, the main goals should be to produce herbicides that are more specific towards target plants, that can be applied in low doses, and that are rapidly degraded and inactivated by the environment. Until recently herbicide treatment was made following the pre-emergence (PrE) procedure, namely the herbicide was spread over the soil after sowing, but before crop germination.

Continuous research progress has produced herbicides that are so selective and efficacious that they may be applied at very low concentrations (down to $1\,g\,ha^{-1}$ rather than the $500–2000\,g\,ha^{-1}$ of traditional pesticides), directly on foliage, and only when the danger threshold is approached. Thus PrE treatments have been superseded by post-emergence (PoE) treatments in which herbicide application takes place after germination.

A PoE herbicide can be defined as a foliage-applied product used to control weeds that have emerged in competition with the developing crop. PoE herbicides' high selectivity make it necessary to treat specific crops with specific compounds, (i.e. compounds that are well tolerated by the crop but not by the weeds), thus avoiding the more persistent and environmentally less safe PrE herbicides. However, many PoE herbicides retain residual activity in the soil and can thus control late-germinating weeds. The more used classes of PoE herbicides, which are predicted to become increasingly popular in the near future, are listed in Table 1.

The opportunity offered to farmers, to use small amounts of chemicals with a very low toxicity to mammals, has encouraged a fast worldwide diffusion of PoE herbicides as shown in Figure 1.

Even though the risk to humans of ingesting toxic doses of herbicide residues in food seems low, it is important to monitor herbicide levels in the environment and food commodities because of their extensive use and documented occurrence both in the environment and in foods. By ''residues'' is meant low levels of pesticides and their metabolites that remain in food after application. To protect the health of their consumers, most countries

Table 1 Principal PoE herbicide classes and their primary target site of action

Chemical class	Primary target site of action
Sulfonylureas	acetolactate synthetase
IMIs	acetolactate synthetase
Aryloxyphenoxypropionic acids/esters	acetyl-CoA carboxylase
DPhEs	protoporphyrinogen oxidase
Triazolopyrimidine sulfonanilides	acetolactate synthetase
Phenylaminosulfonylureas	acetolactate synthetase
Cyclohexanediones	acetyl-CoA carboxylase

CoA, coenzyme A.

have introduced laws not only governing the use of pesticides but also setting limits for the levels of pesticide residues that can be tolerated in drinking water and foods. The maximum residue limit (MRL) is the maximum acceptable level of a residue that regulatory authorities will tolerate on the basis of toxicological food intake data.

2 REGULATIONS

The ''Maximum Admissible Concentration'' of pesticides in drinking water is defined by the European Community Water Directive as $100\,ng\,L^{-1}$ for individual pesticides and as $500\,ng\,L^{-1}$ for the sum of pesticides.[1] Pesticide residues in food are regulated at the international and national levels according to the toxicity of the pesticide and the human intake of a particular crop. The levels of pesticide residues are controlled by the MRLs, established by each country. These sometimes cause conflict because residue levels acceptable in one country can be unacceptable in another. This problem of MRL harmonization has been mainly dealt with by two international organizations: the European Union (EU) at European level, and the Codex Alimentarius Commission,[2,3] an international body established in 1962, to implement the Joint FAO/WHO Food Standards Program. Nations that are members of the Food and Agriculture Organization (FAO) and World Health Organization (WHO) may become members of the Codex Alimentarius Commission.[4]

The EU directives promulgated between 1976 and 1989 achieved only partial harmonization because they fixed the MRLs of only 64 out of the more than 600 active ingredients on the market.[5] In 1990, the EU issued a new directive that fixes MRLs for all EU countries, thus eliminating the higher MRLs acceptable in some countries.[2,3]

There are EU directives that establish sampling and analytical methods for the official control of pesticide

Figure 1 Herbicide diffusion in the world. (Source: United States Environmental Protection Agency (USEPA).)

residues in fruit, vegetables, and products for human consumption. Also, an EU directive published in 1991 covers the marketing of pesticide products. This demands a large number of studies on residues before an active ingredient can be authorized at European level.[3]

In the USA, food safety is an important responsibility not only of the Food and Drug Administration (FDA), but also of the United States Department of Agriculture (USDA), the USEPA, and other agencies at the federal, state, and local levels. The USEPA registers or approves the use of pesticides and establishes a tolerance level if the use of a pesticide may lead to residues in food.[6]

The FDA is responsible for enforcing the USEPA-established pesticide tolerances for foods shipped in interstate commerce, with the exception of meat and poultry, which are the responsibility of the USDA.[7]

The detection and determination limits required for routine analytical methods for herbicide residues should not be higher than 10–50% of the corresponding MRL as recommended by Frehse.[8] This puts the highest requirements of methods for the determination of residues in drinking water, where the maximum permissible levels are sometimes as low as $100\,ng\,L^{-1}$, and in food.

3 ANALYTICAL METHODS FOR DETERMINATION OF POST-EMERGENCE HERBICIDES IN ENVIRONMENTAL AND FOOD SAMPLES: GENERAL

In order to analyze PoE herbicides, knowledge of the physical and chemical properties of the classes of pesticides is essential to develop the best residue analytical methods with the most appropriate instruments.

The sequence of steps in the analysis are the sample preparation and determination. The sample preparation consists in the extraction and cleanup procedures.

3.1 Extraction

The extraction of PoE residues from the matrix is a requisite for almost all the methods of analysis, either for the whole body of water sample or for solid or semisolid substances. A wide variety of extraction procedures have been used to remove PoE residues from environmental water, soil, and food.

For liquid samples, extraction will be accomplished by liquid–liquid extraction (LLE) partition using an organic solvent nonmiscible with water, by solid-phase extraction (SPE), or solid-phase microextraction (SPME) techniques, and supercritical fluid extraction (SFE) after enrichment on a precolumn packed with a polymeric phase.

Extraction of a solid or semisolid sample depends on the polarity of the PoE residues as well as the polar matrix. If the PoE residues are ionic or polar compounds, samples are usually extracted by mixing with pH-adjusted water or organic solvent diluted with pH-adjusted water using a shaker, blender, Polytron™, sonication, or Soxhlet. For less polar PoE residues, organic solvents (acetonitrile, methanol, acetone, ethyl acetate) and solvent mixtures are ground with the samples. The extraction solvents and residual solids are then separated by filtration or centrifugation.

Newer techniques for the extraction of PoE residues are:

- SFE using a supercritical fluid, usually carbon dioxide, with or without organic modifier (methanol, acetonitrile);
- microwave-assisted extraction (MAE), which has the advantages of lower solvent consumption and greater speed than conventional extraction;
- soil column extraction (SCE), using organic solvent mixed with pH-adjusted water. This technique reduces the complexity of the analytical method and the sample preparation time.

3.2 Cleanup Procedures

An extraction technique is selected to obtain the highest recovery for a wide range of contaminants. Therefore, the extract is likely to contain a high proportion of coextracted material. The goal of cleanup is to remove as much interfering coextractive material and as little of the analyte as possible. A cleanup procedure for sample extracts is often required, depending on the type of compound and kind of sample to be analyzed and for the selectivity of the analytical equipment used in determination.

Liquid–liquid partition (LLP) is the most common first step in cleaning up the extract to remove water-miscible solvents or reduce the amount of fat present in the extracts. The extraction efficiency can be enhanced by adding sodium chloride or sodium sulfate to salt out the analyte. If the PoE analyte is an acid, it can be brought into the aqueous or organic phase by modulating the pH value.

The cleanup techniques most commonly employed for extracts containing PoE residues are column chromatographic SPE systems and gel permeation chromatography (GPC).

Open-column chromatography uses columns packed with florisil, silica or alumina in the normal phase, or with reversed-phase (RP) columns of C_{18}, cyanopropyl, phenyl

or graphitized carbon black (GCB). These columns can be prepared in the laboratory, or use can be made of SPE cartridges.

To some extent, interference can be overcome by using size-exclusion chromatography (SEC) with gel, for example, GPC. The most useful gel for PoE cleanup is BioBead SX-3. A disadvantage of the GPC step is that it is slow and requires the use of comparatively large volumes of solvent with the attendant risk of contamination.

3.3 Determination

Nowadays the classic techniques for determination and quantification of PoE residues in environmental and food samples are GC and HPLC. GC and HPLC, in conjunction with mass spectrometry (MS), can be powerful tools for confirmatory analysis. IAs are now being seen as useful supplements to classical chromatographic analytical systems. IA provides a specific reaction with a compound or a group of compounds, which could reduce matrix effect and the need for sample cleanup and concentration. Classical direct current (DC) polarography and fast scan differential pulse voltammetry (FSDVP) have also been applied.

3.3.1 Gas Chromatography

GC on a packed column or capillary column is still the most common separatory technique in PoE residue analysis, and the most common detection systems are nitrogen–phosphorus detection (NPD), electron capture detection (ECD), atomic emission detection (AED), and flame ionization detection (FID). The direct analysis of PoE acids by GC is obstructed because of their acidic character and low volatility. Therefore, derivatization is usually necessary before GC analysis. In environmental applications, the most-used derivatization procedures employ diazomethane, 2,2,2-trifluoroethanol (TFE), pentafluorobenzyl bromide, methyl, ethyl and butyl chloroformate, and trifluoroethyl bromine.

3.3.2 High-performance Liquid Chromatography

Nowadays, HPLC is being extensively used in PoE residue analysis and related areas where the chemicals of interest are frequently of low volatility for GC separation. Briefly, HPLC methods for determination of the PoE residue in environmental samples could employ RP chromatography with C_{18}, C_8, cyanopropyl, and phenyl columns followed by ultraviolet (UV) absorption, UV diode array detector (DAD), fluorimetric (FI) detection, amperometric electrochemical detection (AD) and photoconductivity detection (PCD). Isocratic or gradient elution with a large change in mobile-phase composition is also used. Buffer solutions with the pH adjusted below the pK_a values of the acidic compounds are commonly employed. For ionic PoE residues an ion-pairing mechanism has been reported.[9]

3.3.3 Hyphenated Techniques

The confirmation of all results is a fundamental requirement of PoE residue analysis, as in all other trace analyses. As chromatography is a poor identification technique, hyphenated techniques have been developed and have gained popularity for increasing the selectivity and the certainty of identification.

MS, coupled with GC or HPLC, is being used more often.

3.3.4 Immunoassays

Although IAs have been widely used in clinical analysis since the 1960s, their application in pesticide residue determination is recent. At the present time, PoE residual determination has only been developed for IMIs and for diclofop-methyl. Application of IAs in PoE analysis will probably increase in future. This technique has great potential because it offers many advantages including sensitivity, specificity, and analysis speed.

However, the disadvantage is that each kit is specific to a single analyte.

3.3.5 Other Techniques

Nitropesticides have been studied with the aim of establishing their electrochemical reduction and adsorption characteristics at the mercury-drop electrode with regard to the medium acidity and the compound structure.

4 IMIDAZOLINONE HERBICIDES

4.1 Chemical and Physical Properties

The chemical structures, names, and chemical abstracts service registry numbers of IMI herbicides are reported in Table 2. The basic physical, chemical, and other properties of the IMI herbicides are listed in Tables 3–5. The data in these tables are taken from *The Pesticide Manual*.[10]

The IMIs are a relatively new class of herbicides, used to control a wide spectrum of broad-leaved weeds and grasses in a variety of agricultural commodities.[11] These herbicides are very potent weedkillers and are used in doses that are substantially lower than conventional herbicides.

The water solubility and vapor pressure of the IMI carboxylic acids are low, whereas the octanol–water

	**imazmethapyr** (*R,S*)-5-methyl-2-(4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)nicotinic acid	–

partition coefficients are pH dependent. At pH 4, the IMI carboxylic acids are neutral and therefore lipophilic, whereas at pH 7 the carboxylic acids are ionized. The pK_a values of several IMI herbicides lie between 1.9 and 11.4. Up to three inflection points have been observed in the titration of IMIs. The IMI ring is amphoteric and behaves as a weak base or a weak acid. The first inflection point corresponds to protonation of the IMI ring at pK_1 of about 1.9–3.3, whereas the second reflects ionization of the carboxylic acid at pK_2 values around 3.6–3.9. The third inflection point, determined only for imazapyr, corresponds to IMI ring deprotonation at a pK_3 of about 11.4.

The hydrolytic stability of the IMI ring is pH dependent. At environmentally relevant pH and temperature, hydrolysis is very slow. At pH less than 7, the IMI ring is stable.

As shown in Table 2, the members of this class of herbicides have similar structural features centered around the IMI ring and an attached aromatic system bearing a carboxylic acid moiety. IMIs have an excellent activity against annual and perennial grasses and broad-leaved

weeds when applied either PrE or PoE. They function by inhibiting acetohydroxy acid synthase (AHAS), the feedback enzyme in the biosynthesis of branched-chain essential acids.[12–14] This enzyme is not present in animals.

In order for a herbicide to kill plants, the chemical must be adsorbed and translocated to the site of action. In the case of IMIs, the site of action is the AHAS enzyme, which is concentrated in plant meristematic tissues. IMIs enter plants through the root or shoot tissue and are then translocated throughout the plant via the xylem, the water transport system, or the phloem, the sugar transport system. The mechanism by which IMIs are adsorbed and retained within plant cells is called

ion-trapping.[15] The pH gradient that occurs within plants is typically pH 4.5–5 outside the cell and 7–7.5 inside the cell.[16] Although IMIs are water-soluble compounds, under acidic conditions the molecules are relatively more lipophilic and, as such, are able to diffuse across cell membranes. Once inside, the molecule becomes charged in the alkaline environment with a concomitant decrease in lipophilicity. Because the charged form of the IMI is slower to diffuse across the plasma membrane, the compound accumulates, or is trapped within the cell.

Imazapyr is a broad-spectrum herbicide that controls most annual and perennial grasses and broad-leaved weeds, woody brush, and deciduous trees in noncrop areas such as railroads, utility areas, pipeline and highway rights-of-way, utility plant sites, petroleum tank farms, pumping installations, fence rows, storage areas, and nonirrigation ditchbanks. It is used to establish and maintain wildlife openings, to prepare sites for conifer planting, and to release conifers from competing vegetation. Imazapyr has also been developed for use in sugar cane and plantation crops, such as rubber and oil palm.

Imazapyr PoE application is preferred in most situations, particularly for the control of perennial weeds. For maximum herbicidal activity, imazapyr should be applied when the weeds are growing vigorously.

Imazaquin was the first IMI to be widely accepted as a herbicide for broad-spectrum weed control. Initial results have demonstrated that imazaquin can be applied preplant incorporated, PrE, or PoE for the control of many difficult-to-control soybean weed species.

In early testing, it was discovered that imazaquin applied as a PoE treatment uniquely provided both burndown of susceptible weeds present and residual control of later-germinating weeds.

Imazethapyr is a selective IMI used to control a wide spectrum of broad-leaved weeds and grasses in soybeans and several leguminous crops. Imazethapyr is a uniquely flexible herbicide that can be applied early preplant, at planting, or PoE. The herbicide is very effective in no-till as well as conventional tillage situations. Residual season-long control was recognized as an important feature of imazethapyr, and in general it was determined that optimum application rates for soil and PoE applications are the same, and efficiency is not affected by soil type or characteristics.

Imazamethabenz-methyl is a selective, PoE herbicide used to control weeds in cereal crops. It controls many of the economically important weeds that infest wheat, barley, and rye. Imazamethabenz-methyl is applied as ester, but it is the acidic form that is herbicidally active.

The first sign of herbicidal activity is chlorosis of the youngest leaves; later in the season the whole plant becomes necrotic or remains as a small, noncompetitive weed at the base of the crop.

Imazamethabenz-methyl also has soil residual activity; thus, susceptible weeds that germinate after application can be controlled.

The IMI herbicides have been subjected to exhaustive toxicological studies to determine their toxicity to mammals and other nontarget organisms and to evaluate the potential hazard of handling and applying these herbicides. As demonstrated by the results of those studies, the IMIs have a low toxicological potential, partially because they act by inhibiting a biosynthetic process at a site present only in plants. In addition, these herbicides are excreted rapidly by rats before they can accumulate in the tissues or blood.

4.2 Analytical Methods for Imidazolinone Analysis

4.2.1 Extraction

The extractive solvent and the method used depend on the nature of sample. For liquid samples, particularly for groundwater and surface water, extraction has been obtained by using a 6-mL SPE column packed with 1 g of Baker Light-load Octadecil or Waters Sep-Pak Plus Environmental,[17] and 1 g of Carbograph-1.[18] Extraction from solid samples depends on the polarity of the pesticides as well as the sample matrix. For food samples, extractions are usually performed by mixing them with methanol[19,20] or a methanol–water (25 : 75) solution acidified with HCl.[21] For solid samples such as environmental soils, extraction can be carried out in two ways: (1) mechanically stirring the sample with different organic solvents, such as methanol, acetone, ethyl acetate, diethyl ether, 2-propanol, ethanol, and dichloromethane,[22] ammonium hydrogen carbonate,[23] 0.1 mol L^{-1} sodium carbonate,[24] methanol–water (50 : 50, v/v),[25] 0.5 mol L^{-1} NaOH, and methanol;[26] (2) extracting imazamethabenz-methyl[22] and imazaquin[27] by SFE, usually using CO_2 with methanol as organic modifier.[22] Two new techniques that have been developed to extract IMIs from solid samples are MAE[28–30] and SCE.[18] Stout et al.[28,29] found that MAE with NH_4OAc/NH_4OH (0.1 mol L^{-1}, pH 10) as the extractant achieved the best results with different soils. They applied the same technique, using several types of extractants: (namely H_2O, CH_3OH, 10% H_2O/CH_3OH, and 0.1 mol L^{-1} NH_4OAc/H_2O) to the extraction of imazethapyr, its hydroxy metabolite, and the glucose conjugate from 11 different preparations.[30] *m*-imazamethabenz, *p*-imazamethabenz, *m*-,*p*-imazamethabenz-methyl, imazapyr, imazaquin and imazethapyr have been extracted by SCE, using as the extraction phase a methanol–ammonium carbonate mixture (0.1 mol L^{-1}, pH 8.2, 50 : 50, v/v).[18] The SCE technique makes the sample preparation method efficient and economical, and the preparation time is reduced.

Extraction and cleanup procedures used in the determination of IMI herbicides are shown in Table 6.

4.2.2 Cleanup

The extract obtained during an extraction step usually has to undergo a further cleanup procedure. After solid samples have been ground in the presence of a mixture of polar solvent and water-immiscible solvent, the resulting mixture is cleaned up by LLP and/or column chromatography.

The solvent partition system used in IMI residue analysis includes dichloromethane,[24,26] and hexane.[20] For the solvent partition system of oil obtained after the filtrate evaporation under reduced pressure, Mortimer and Weber[19] use 1 N NaOH and 25 mL of hexane–EtOAc (1 : 1). The aqueous layer was removed, and the organic layer was extracted with an additional 10 mL of 1 N NaOH. The combined aqueous layers were first back-extracted with 15 mL of hexane–EtOAc (1 : 1), acidified to pH 3 with 10 N H_2SO_4, and extracted with two 20-mL portions of dichloromethane. Currently SPE is predominant in the cleanup of IMI residues. One or more SPE columns packed with various types of sorbents have been developed and applied. The nonpolar material octadecyl (C_{18}) is the most commonly used sorbent in IMI analysis.[20,21,23,28,30] For a better cleanup the C_{18} sorbent is used in tandem with an SCX cartridge,[30] and an SAX cartridge.[23] Curran et al.[26] use solid-phase octyl (C_8) and aromatic sulfonic acid cartridges for imazaquin cleanup from soil. A sorbent of diol-bounded silica in a single column has also been used[19] for the cleanup of imazethapyr in soybeans. A GCB, Carbograph-1, has been evaluated[18] as a cleanup system in the soil analysis of six main IMIs.

4.3 Determination

All of the analytical methods for IMI residues are based on chromatography, mainly GC and HPLC, hyphenated and immunochemical techniques (see Tables 7–10).

4.3.1 Gas Chromatography

Two gas chromatographic methods have been developed for the determination of imazethapyr in soybeans[19] and soil.[26] Both make use of a capillary column with a bonded phase of low polarity (DB-5) and NPD to determine the residue. For GC analysis, the method[19] exploits the ready cyclization of the nonvolatile acid imazethapyr to the volatile imidazoisoindol-3,5-dione using an excess of dimethylaminopropylethylcarbodiimide hydrochloride.

Table 7 shows examples of IMI determination by GC, and Figure 2 presents the chromatograms of imazethapyr in soybeans analyzed by GC/NPD.

4.3.2 High-performance Liquid Chromatography

HPLC is being extensively used in IMI analysis. The advantage of HPLC over GC is that the quantification of acidic IMI is carried out without need of derivatization.

The diverse methods used to determine IMI in environmental samples are shown in Table 8. Summarizing them, HPLC methods for the determination of residues employ RP chromatography with C_{18}[18,23–25] or C_8[26] columns. For increasing the selectivity in the analysis of imazapyr and imazethapyr from soil, Nováková[24] employs a column-switching method using two separation columns. Whether in isocratic[23,25,26] or gradient mode,[18,24] all mobile phases are formed from aqueous solutions acidified with different acids: formic,[18] phosphoric,[23–25] and acetic.[26] UV detection, usually operated in the range 235–260 nm, is the only detection method utilized in the analysis of IMI residues. Table 8 summarizes representative papers using this technique. HPLC/UV chromatograms obtained by analyzing groundwater, lake, and river water spiked with six IMI herbicides are shown in Figure 3.

4.3.3 Hyphenated Techniques

The successful combination of MS with GC and subsequently with liquid chromatography (LC) has enabled not only the determination of IMI pesticides but also the identification of their residues at trace levels. The three modes of GC/MS that have been used are electron impact (EI), positive chemical ionization (PCI), and negative chemical ionization (NCI). GC/MS in EI mode using selected ion monitoring (SIM) is used in the determination imazethapyr in soybeans,[19] imazamethabenz-methyl in soil,[22] and imazapyr in corn.[21] PCI and NCI are good alternative ionization methods which offer better selectivity and/or sensitivity than EI.[22] In the work proposed by Stout et al.,[29] the authors demonstrate that analyte detecting with the sensitivity and specificity of GC/ECNCI/MS reduces the required cleanup. Stout

Figure 3 HPLC/UV chromatograms obtained by analyzing (a) 0.5 L of river water and (b) 0.5 L of river water, spiked at 1000 ng L^{-1} (*m*-imazamethabenz at 200 ng L^{-1}). Peaks: 1 = imazapyr, 2 = *m*-imazamethabenz, 3 = *p*-imazamethabenz, 4 = *m*-, *p*-imazamethabenz-methyl, 5 = imazethapyr, 6 = imazaquin. (Reproduced by permission of American Chemical Society from A. Laganà, G. Fago, A. Marino, *Anal. Chem.*, **70**, 121–130 (1998).)

et al.[21] wanted to evaluate the potential utility of GC with EI/MS on a less expensive GC/ECNCI/MS for the determination of imazapyr in corn.

HPLC coupled with MS provides the analyst with a powerful tool for IMI residue determination. Interfacing these devices is most commonly done by employing a particle beam (PB) or electrospray ionization (ESI) technique. HPLC/PB/MS has been applied for confirming imazamethabenz-methyl[22] in soil. By combining LC with electrospray ionization/mass spectrometry (ESIMS) or electrospray ionization tandem mass spectrometry (ESIMS/MS)[31] IMIs present in water can be monitored simultaneously at the 1 ppb level with only a simple filtration prior to analysis. The same authors developed a method for the rapid and direct determination of imazethapyr and imazmethapyr in soil by using LC/ESIMS and LC/ESIMS/MS;[28] an analytical procedure based on LC/ESIMS[30] is employed for targeted imazethapyr and its metabolites in a wide range of crop commodities. LC/ESIMS is a selective approach particularly suitable for confirming the presence of imazapyr, *m*-imazamethabenz, *p*-imazamethabenz, *m*-, *p*-imazamethabenz-methyl, imazethapyr, and imazaquin in two types of samples:[18] (1) for groundwater, lake water, and river water samples the analysis is made by HPLC/ESIMS in full-scan mode; (2) for soil samples LC/ESIMS under three ion SIM conditions is employed.

Table 9 shows examples of IMI herbicides determined by these hyphenated techniques and Figure 4 depicts chromatograms from LC/ESIMS of an unfortified, and a fortified soil with imazethapyr at the 1 ppb level.

4.3.4 Immunoassay

IAs are now being seen as useful supplements to classical chromatographic analytical systems. The near future will also see an integration of immunochemical and classical procedures.

IA provides rapid, sensitive, and cost-effective analysis for a variety of IMI residues. The main disadvantage is that only one compound at a time can be determined. The usefulness of these techniques is experienced during screening analysis when a large number of samples have to be analyzed in parallel for a simple analyte within a short time. Among the different IA procedures for determining the IMI residue, the most explored is enzyme-linked immuno-adsorbent assay (ELISA).

Figure 4 Chromatograms from LC/ESIMS of (a) blind Indiana soil with apparent imazethapyr at 0.17 ppb and (b) Indiana soil fortified with imazethapyr at 1 ppb. (Reprinted from *The Journal of AOAC International*, **80**, 426–432 (1997). Copyright, 1997, by AOAC International.)

ELISA is applied to the analysis of surface runoff water[17] and to the analysis of more complex matrices such as agrochemicals[33] and cereal grain.[20] In the analysis of imazaquin[33] and imazamethabenz,[20] erroneous results could be produced by matrix effects or the inability to differentiate between structurally similar compounds (cross-reactivity).

For tap and groundwater, Lee and Durst[34] have developed an assay based on sequential competitive binding of imazethapyr and liposomes for a limited number of antibody binding sites. A capillary tube with immobilized antibody was used as the immunoreactor column. Liposomes that entrap fluorescent molecules as the detectable label provide instantaneous, rather than time-dependent, enhancement, common with enzyme IAs. Bioassay techniques are applied for the determination of imazaquin and imazethapyr in soil.[26,32] In the method proposed by O'Bryan et al.[32] three corn-root bioassays were evaluated for detecting imazaquin in soil. Two techniques, one which utilized a cone-shaped tube as a growth container and another a petri dish, were compared to a method that utilized a thin layer of soil between two 20×20 cm glass plates. Representative examples are summarized in Table 10.

5 ARYLOXYPHENOXYPROPIONIC ACIDS/ESTERS

5.1 Chemical and Physical Properties

Since the late 1980s, many heterocyclic oxyphenoxypropionic acid derivatives have been prepared as a new class of selective herbicides for the control of graminaceous weeds in broad-leaved crops and tolerant cereals. Esters of aryloxyphenoxypropionic acids are a new series of highly selective PoE herbicides, often termed ''phenoxyphenoxys''. In the treated plants they decompose fairly rapidly, yielding the corresponding free acids as the main metabolites.

The chemical structures, names, and chemical abstracts registry numbers of aryloxyphenoxypropionate (ArPP) herbicides are shown in Table 11. Tables 12–14 enumerate the chemical, physical, and other properties of ArPP herbicides.

Considerable progress has been made towards understanding the mode of action of the ArPP herbicides. Earlier studies suggested that these compounds disabled de novo fatty acid biosynthesis, but no specific site of action was identified.[35] Recently, it has been demonstrated that they specifically inhibit acetyl-CoA carboxylase in susceptible plants. This enzyme catalyzes the adenosine triphosphate (ATP)-dependent formation of malonyl-CoA from acetyl-CoA and bicarbonate, that is the first committed step for fatty acid synthesis de novo.

In spite of their different structures they show the same symptomatology and selectivity of herbicidal action. In fact, they are PoE herbicides that are used for the control of annual and perennial grasses in a large variety of broad-leaved crop plants.[36]

ArPP esters form colorless crystals or odorless solids, except for fluazifop-butyl which is a pale straw-colored liquid. This class of compounds is relatively stable in acidic media (pH 3), and in some cases in neutral conditions, undergoing slow hydrolysis to the free acid between 30 and more than 1000 days. This process is much faster in alkaline media (pH 9), ranging from 2.2 to 60 h. The pK_a values of the free acids are between 2.9 and 3.4.

ArPPs are selective herbicides with a systemic action. They are absorbed principally by the leaves, and in some cases by the roots, to undergo rapid transformation into the acidic form which is then translocated throughout the plant via the xylem or phloem system, accumulating in the meristematic tissues. All these compounds can be regarded as heterocyclic homologs of the wild oat herbicide diclofop, in which the terminal dichlorophenyl ring is replaced by a heterocycle, such as pyridine, quinoline, quinoxaline, benzothiazole, or benzoxazole. ArPPs posses a chiral center and exist as a mixture of two optical isomers. The (*R*) enantiomer of fluazifop-butyl was the second case of a herbicide in which the introduction of the resolved form largely replaced the racemate. Although biological activity resides exclusively with the (*R*) enantiomer in PoE applications, the (*R*) and (*S*) enantiomers show equivalent activity when applied in PrE. This has been shown to be due to microbial conversion of the (*S*) to the (*R*) enantiomer in the soil.

The main uses are on soybeans, sugar beet, and cotton. Particular uses include control of volunteer cereals and other grass weeds in wheat, barley, rye, legumes, oil seed rape, sunflowers, fodder beet, flax, alfalfa, peanuts, beetroot, lettuce, spinach, potatoes, cucumber, peas, tomatoes, fennel, and strawberries.

With so many products already on the market or becoming available for the same use on the same crops in a relatively short period of time, severe competition is inevitable. Some efforts have been made to search for new applications.

Thus fenoxaprop-ethyl is only marginally selective in wheat, but addition of the safener fenchlorazole-ethyl has allowed the use of the herbicide on all wheat varieties except durum wheat. Racemic fenoxaprop-ethyl is formulated with the safener in a 4:1 ratio, whereas the active (*R*) isomer utilizes a 2:1 ratio. The safener does not influence either foliar uptake of the herbicide by wheat plants, or the degree of inhibition of acetyl-CoA carboxylase. However, levels of fenoxaprop-ethyl and of its herbicidally active free acid in shoot tissues of wheat decrease more rapidly when applied with fenoxaprop-ethyl; at the same time the formation of inactive metabolites of the herbicide increases.

The ArPPs have undergone many tests to determine their toxicity to mammals in order to prevent serious hazard to farmers. Test conducted on rats have shown that in most cases the ArPP is metabolized into the free acid and then excreted within 3–7 days in urine and feces.[10] The toxicity class according to WHO is III for all compounds except for haloxyfop, which is II.[10]

5.2 Analytical Methods for Aryloxyphenoxypropionate Analysis

5.2.1 Extraction

Table 15 summarizes extraction and cleanup procedures used in the determination of ArPP herbicides.

Currently SPE is predominant in analytical methods used for ArPP herbicidal residues in water matrices. Conventional LLE with dichloromethane has been used in the monitoring of diclofop and haloxyfop,[37] and diclofop-methyl[38] in groundwater.

Different SPE methods have been developed using C_{18} bonded-silica cartridges.[39–45] On-line trace enrichment for diclofop-methyl and fluazifop-butyl screening in river water is obtained with a cartridge packed with a polymeric RP material.[46] For the extraction of fenoxaprop in groundwater, Dupas et al.[47] suggest an on-line device that utilizes a precolumn packed with the apolar PLRP-S. The same material is used by Wuchner and Grob.[48] In such work, SFE is employed for the elution of diclofop-methyl, after enrichment on a precolumn packed with a polymeric phase. For the simultaneous extraction of clodinafop, diclofop, fenoxaprop, fluazifop, haloxyfop and quizalofop from drinking, spring, and groundwater, Laganà et al.[49] employ three different SPE systems:

- a disposable SPE cartridge packed with Carbograph-1;
- a LiChrolut-EN cartridge, an ethylvinylbenzene–divinylbenzene (DVB) resin;
- an SPE disk, made of polystyrene–divinylbenzene (PSDVB).

Chromatograms obtained by analyzing 1 L of a groundwater sample spiked with six ArPPs, using two different SPE systems, are reported in Figure 5.

For solid samples, extraction with a water-miscible solvent is necessary. When the analyzed sample is food, the subsample can be homogenized with acetone,[50–53], acetone–ethanol–2 mol L^{-1} HCl (2 : 1 : 1, by vol),[54] 0.1 mol L^{-1} NaOH,[55] 0.2 mol L^{-1} NaOH in methanol,[56]

[a] PRP-1, polymeric RP material; PLRP-S, copolymer styrene divinylbenzene.

water, is adsorbed on the surface of activated florisil to obtain a free-flowing powder, which is extracted in a glass column with ethyl acetate or dichloromethane–acetone (90:10, v/v). The method proposed by Laganà et al.,[60] for sample preparation involves a simple treatment of the soil sample via isolation and trace enrichment of fluazifop, haloxyfop, and diclofop by SCE.

Several methods have been proposed for the extraction of ArPPs from soil samples. These methods are as follows: Soxhlet with acetone;[9,61] sonication with water and methanol,[62] acetone–light petroleum (50:50, v/v),[57] 4 mol L^{-1} HCl and acetone–light petroleum (2:1) (10:60, v/v),[57] water and acetone or 6 mol L^{-1} HCl and acetone;[63] and batch extraction with acetone–water–acetic acid (80:19:1, v/v) followed by re-extraction by sonication with 0.1 mol L^{-1} KOH;[64] mechanical shaker with 0.1 mol L^{-1} NaOH,[55] 0.1 mol L^{-1} HCl–methanol (50:50, v/v) and ethyl acetate,[65] dichloromethane and then 0.1 mol L^{-1} NaOH–methanol (50:50, v/v).[66]

5.2.2 Cleanup

In the majority of instances, the initial extract contains a too high level of coextracted interfering compounds to allow direct analysis, and some form of cleanup is required.

In the LLP step, the extraction efficiency can be enhanced by adding sodium chloride to salt out the analytes[50,52–55,61] or sodium sulfate.[57] Dichloromethane is most commonly used in LLP.[52,55,56,65] Solvent mixtures such as petroleum ether and dichloromethane,[51] hexane–diethyl ether (50:50, v/v),[54] and chloroform and light petroleum[57,63] are also used. For ArPP analysis, the most commonly used cleanup techniques are SPE packed with Florisil, alumina, silica gel, GCB, phenyl and cyanopropyl bonded phases, SPE-disk and size exclusion (gel permeation).

An alternative sorbent that is especially effective for cleanup of acidic ArPP herbicides is Carbograph-1,[49,60] composed of nonporous spherical graphite particles. The advantage of using the Carbograph-1 cartridge was that extraction, concentration, and fractionation into classes were possible simultaneously (the acid analytes were separated from the neutral to basic ones by differential elution). The presence of some active centers bearing a positive charge enables Carbograph-1 to behave as both a nonspecific and an anion-exchange sorbent. It follows that anionic ArPP herbicides were specifically adsorbed

Figure 5 HPLC/DAD chromatograms obtained by analyzing 1 L of a groundwater sample spiked with ArPP at the individual level of 100–200 ng L^{-1} by different procedures involving the use of (a) the LiChrolut-EN extraction cartridge and (b) the Carbograph-1 cartridge. Peaks: 1 = fluazifop; 2 = clodinafop; 3 = quizalofop; 4 = fenoxaprop; 5 = haloxyfop; 6 = diclofop. (Reprinted from *J. Chromatogr.*, **796**, A. Laganà, G. Fago, A. Marino, 'Determination of Aryloxyphenoxypropionic Acid Herbicides in Water Using Different SPE Procedures and LC/DAD', 309–318, Copyright 1998, with permission from Elsevier Science.)

on the Carbograph-1 surface via electrostatic forces and that they could be desorbed simply by adding a displacing agent (such as formic acid) to the organic solution. Carbograph-1 behaves like conventional exchangers if the stepwise elution of acidic compounds can be achieved on the basis of the acid strands, by appropriate selection of the displacing agents.

Open-column chromatography using a column packed with Florisil is used to remove the chromatographic interference in the determination of fluazifop-butyl and fluazifop in potatoes, soybeans, and soil samples.[55] The six principal ArPP herbicides in fruit and vegetable samples are subjected to activated silica gel column cleanup.[54] Silica gel is also used for cleanup of fluazifop-butyl and fluazifop in soil.[66] Fenoxaprop and fenoxaprop-ethyl in different soils are purified on a Florisil or alumina cartridge.[65] Diclofop-methyl and its metabolite diclofop were extracted and derivatized, and then the products were purified on a chromatographic column containing alumina, silver–alumina, and Florisil.[57] The bromo derivative of fluazifop-butyl and the pentafluorobenzyl derivative of fluazifop are purified on a chromatographic column containing alumina and Florisil.[63]

A C_{18} extraction disk, used in off-line mode, has been evaluated by Bao et al.[62] for the cleanup of diclofop-methyl. Higher flow rates can be applied with an SPE disk and the extraction time is much shorter.

The large difference in polarities between fluazifop-butyl and fluazifop causes difficulties in the application of the sorbent extraction technology for the simultaneous determination of both compounds from soil extracts. Therefore, in the handling of soil extracts containing fluazifop-butyl and fluazifop, Zanco et al.[9] have developed a combination of a phenyl phase and cyanopropyl-phase cartridges for the cleanup operation.

A method used for the cleanup of ArPP in complex matrices is GPC. It has been used for cleanup in the analysis of diclofop-methyl, fenoxaprop, haloxyfop-ethoxyethyl, quizalofop-ethyl,[50] diclofop-methyl,[52] fluazifop, and fluazifop-butyl.[61] Separation is performed using Bio Beads SX-3, a polystyrene type gel, using solvents such as a mixture of cyclohexane and ethyl acetate (50 : 50, v/v),[52] or cyclohexane and acetone (50 : 50, v/v).[53] A liquid chromatographic step on silica gel was therefore inserted between the GPC and the GC step to filter out polar products.[52] Figure 6 shows a typical GC/ECD chromatogram of a fruit

Figure 6 GC/ECD chromatogram of melon extract fortified with haloxyfop-ethoxyethyl (0.33 mg kg^{-1}), fenoxaprop (0.28 mg kg^{-1}), and quizalofop-ethyl (0.29 mg kg^{-1}). (Reproduced from *J. Chromatogr. A*, **782**, A. Gelsomino, B. Petrovicová, S. Tiburtini, E. Magnani, M. Felici, 'Multiresidue Analysis of Pesticides in Fruit and Vegetables by GPC Followed by GC with Electron Capture and Mass Spectrometric Detection', 105–122, Copyright 1997, with permission of Elsevier Science.)

extract containing haloxyfop-ethoxyethyl, fenoxaprop, and quizalofop-ethyl, cleaned up by gel permeation.

5.3 Determination

Chromatographic methods are most widely used for analytical separation, identification, and quantification of ArPP residues in different matrices.

5.3.1 Gas Chromatography

Table 16 summarizes the column, detector, and DL currently employed in routine GC ArPP residue analysis, and Figure 7 shows chromatograms of diclofop-methyl residues in soil and crops. Capillary GC in combination with selective detectors, mainly ECD[37,41,54,57,59,67] and NPD,[54,55] are the most common techniques for ArPP determination. The use of other detectors, such as FID[48] and AED[52] have been reported in only one case. The GC/AED is one type of spectrochemical method, and the incorporation of a microwave-induced plasma generator and a photodiode array has demonstrated its accuracy, reproducibility and simplicity.

The data on the elemental composition of pesticides available from AED chromatograms makes the information content much higher than that obtained from conventional GC detectors. Several stationary bonded phases have been used in the determination of ArPP in different samples, including different polarities: SE-54,[41,55] HP-1,[52] DB-5,[59] HP-5,[54] and SE-52[45] are nonpolar, and 65% dimethyl–35% diphenylpolysiloxane,[37] DB-1701,[48] OV-17,[57,63] and SPB-608[50] are polar.

The acidic ArPPs in the extract were derivatized with TFE,[37] pentafluorobenzyl bromide,[39,42,43,47] methyl, ethyl, and butyl chloroformate,[41] diazomethane,[55,58,66] and bromine.[63]

Figure 8 is a chromatogram of a groundwater sample spiked with fluazifop and haloxyfop, derivatized to their methyl esters.

5.3.2 High-performance Liquid Chromatography

HPLC is used extensively in ArPP residue determination. HPLC methods employ RP chromatography with C_{18}[40,44–47,49,58,65,66] or C_8[9] columns. For the determination of fluazifop the authors utilize a phenyl-bonded phase,[9] and cyano-bonded phase[40] column.

Gradient elution with a large change in mobile-phase composition is used. Buffer solutions with the pH-adjusted below the pK_a values of the acid ArPP are commonly used to increase the retention capacity of RP sorbents for HPLC separation of acidic herbicides.[40,49,56,58,65]

A possible method with which to increase the separation efficiency and retention capacity for acid herbicides is RP/HPLC under mild conditions, at nearly neutral pH and utilizing an ion-pairing mechanism with the ion-pair reagent tetrabutylammonium hydrogensulfate ($TBAHSO_4$)[9] and triethylamine.[44]

Variable-wavelength UV has been the routinely used detection technique, enabling sufficient sensitivity for most ArPPs to be detected.[9,40,44,58,65] It is usually operated in the range 220–280 nm. The problem of

APCI/NI, atmospheric pressure chemical ionization with negative ion mode of operation; IT, ion-trap.

identification, a characteristic of chromatographic methods, cannot be solved with the application of a UV detector. An increase of confirmation ability has been achieved with the DAD. This technique has been used in the simultaneous HPLC analysis of clodinafop, quizalofop,[49] diclofop-methyl, fluazifop-butyl,[46] and fenoxaprop[47] in aqueous samples. In the determination of fluazifop in soybean oil by HPLC, AD in oxidation mode[56] is used to achieve selectivity and sensitivity.

Table 17 summarizes the column, mobile phase, detector, and DLs currently employed in routine ArPP residue analyses.

5.3.3 Hyphenated Techniques

The identification and confirmation of analytical results is been obtained by combining MS with GC (GC/MS) or subsequently with LC (HPLC/MS). Table 18 summarizes representative papers using hyphenated techniques.

A newly developed scan function and methane gas control system has enabled classical chemical ionization (CI) spectra to be obtained in the IT, thus allowing direct comparison with reference spectra developed on magnetic and quadrupole instruments. Gas chromatography ion-trap mass spectrometry (GC/IT/MS) is used for the determination of diclofop-methyl and fenoxaprop-ethyl in fruit and vegetable matrices,[51] and diclofop-methyl in soil.[62]

Mass selective detection (MSD), using either full-scan mode or SIM, can be employed to achieve selective detection of target pesticides in the presence of a complex matrix. MSD is a highly sensitive and specific technique suitable for environmental organic analysis. The most widely used technique for ArPP residue analyses is MSD with EI ionization. Quantification is usually achieved with the SIM technique. With this technique selectivity is also improved.[38,39,43,45,50,54,55,58,64] Lee et al.[37] have determined diclofop and haloxyfop in groundwater; after esterification with 2,2,2,-trifluoromethanol, the esters are identified by GC with MSD in full-scan mode. In the method proposed by Butz and Stan,[41] for the simultaneous determination of diclofop, fenoxaprop, fluazifop, haloxyfop, and quizalofop in tap water and groundwater, all MS measurements are performed with MSD combined with GC in full-scan mode. MSD in full-scan mode is also utilized for the determination of fluazifop and fluazifop-butyl in groundwater,[41] and of quizalofop-ethyl in fruit and vegetables.[67]

To date only one report[60] discusses HPLC coupled with MS. The aim of this work was to attain lower levels of detection while maintaining sufficiently high specificity in order to unequivocally identify and quantify selected target ArPPs in soil samples; all data were obtained using HPLC/ESIMS in NI mode. Figure 9 shows a SIM chromatogram obtained in NI discharge on electrospray interface coupling HPLC to MS of a soil sample spiked with fluazifop, haloxyfop, and diclofop.

5.3.4 Other Techniques

IAs are now being seen as useful supplements to classical chromatographic analytical systems. Schwalbe et al.[68] describe the development of enzyme IA and fluoro-IA for the herbicide diclofop-methyl in soil, urine,

Figure 9 HPLC/ESIMS chromatogram obtained by Pomaia soil sample spiked with ArPP herbicides at the 1 ng g^{-1} level using (a) full-scan and (b) time-scheduled SIM conditions under negative ion (NI) mode: (1) fluazifop, (2) haloxyfop, and (3) diclofop. (Reprinted from *Anal. Chim. Acta*, **375**, A. Laganà, G. Fago, A. Marino, M. Mosso, 'SCE Followed by LC/ESIMS for the Efficient Determination of Aryloxyphenoxypropionic Herbicides in Soil Samples at ppb Levels', 107–116, Copyright 1998, with permission from Elsevier Science.)

serum, wheat, soybeans, and sugar beet. To produce antibodies against the herbicide, rabbits were immunized with a conjugate of diclofop acid and bovine serum albumin, which was prepared by use of a water-soluble carbodiimide. The resulting antisera showed a high specificity towards the (dichlorophenoxy)phenoxy moiety of the herbicide, which was demonstrated by the determination of the cross-reactions of structurally related compounds.

6 DIPHENYL ETHER HERBICIDES

6.1 Chemical and Physical Properties

The *p*-nitro DPhE herbicides are commonly known as the DPhE herbicides. This class of herbicides is mainly composed of esters, but a few compounds are acids or have an acidic behavior, with pK_a values between 2.7 and 3.8. They are yellow to brown crystals,

Table 19 Chemical structures, IUPAC-recommended names[10] and Chemical Abstracts Service registry numbers of DPhE herbicides

Chemical structure	Name	CAS
	**acifluorfen** 5-(2-chloro-α,α,α-trifluoro-*p*-tolyloxy)-2-nitrobenzoic acid	[50594-66-6]
	**aclonifen** 2-chloro-6-nitro-3-phenoxybenzenamine	[74070-46-5]
	**bifenox** methyl 5-(2,4-dichlorophenoxy)-2-nitrobenzoate	[42576-02-3]
	**bifenox acid** 5-(2,4-dichlorophenoxy)-2-nitrobenzoic acid	N/A
	**chlornitrofen** 4-nitrophenyl 2, 4, 6-trichlorophenyl ether	[1836-77-7]
	**fluoroglycofen-ethyl** ethyl *O*-[5-(2-chloro-α,α,α-trifluoro-*p*-tolyloxy)-2-nitrobenzoyl]glycolate	[77501-90-7]
	**fomesafen** 5-(2-chloro-α,α,α-trifluoro-*p*-tolyloxy)-*N*-methylsulfonyl-2-nitrobenzamide	[72178-02-0]
	**lactofen** ethyl *O*-[5-(2-chloro-α,α,α,-trifluoro-*p*-tolyloxy)-2-nitrobenzoyl]-DL-lactate	[77501-63-4]
	**oxyfluorfen** 2-chloro-α,α,α-trifluoro-*p*-tolyl 3-ethoxy-4-nitrophenyl ether	[42874-03-3]

presenting in some cases a slightly aromatic odor. All compounds of this class are stable in slightly acid or slightly alkaline media (pH 5–9), but are hydrolyzed quite rapidly above pH 9. The exception is fomesafen which is stable even at pH 11. DPhE herbicides have been subjected to many studies in order to understand their mode of action. Initial studies into the mechanism of action of these compounds suggested they were interfering with some aspect of photosynthetic electron transport.[69–73] Then Bugg et al.[74] obtained evidence

which indicated the site of inhibition by the DPhE was in the plastoquinone-Cyt *f* region between PS-I and PS-II. However, there is evidence to indicate the inhibition of electron transport is a secondary effect.[75–81] The most recent studies have determined that the site of action is protoporphyrinogen oxidase, and that the R group at the 3′ position of the DPhE molecule is an absolute requirement for the short term (8 h) expression of herbicidal activity.[82] However, the nature of the R group is also important.[82]

Structure/activity studies have shown that the highest biological activity of DPhE is generated by the substituents 2-Cl, 4-CF_3, 4-NO_2 and various structures in the 3′ position (see Table 19). DPhE derivatives having oxime substituent groups at the 3′ position were found to exhibit high herbicidal activity and soybean selectivity.[83]

DPhEs are systemic contact herbicides, absorbed more readily by the foliage, and especially by the shoots, then by the roots with very little translocation. In some cases herbicide activity is enhanced by sunlight. DPhE symptomatology is necrosis of shoot and root meristems with rapid desiccation of stems and leaves following PoE treatment of sensitive species.

This class of compounds is mainly used for PrE or PoE control of a wide spectrum of annual broad-leaved weeds and grasses in soybeans, peanuts, rice, and cereals. Particular crops include also potatoes, carrots, peas, maize, peppermint, onions, and a variety of tropical and subtropical crops.

The WHO toxicity class is III for all compounds except lactofen, which is WHO IV. Tests conducted on rabbits have demonstrated that DPhEs can be slight to moderate eye and skin irritants, except acifluorfen, which is a severe eye irritant. From studies of oral application in rats, it appears that fast and almost complete absorption and excretion occurs. Multiple applications did not indicate a cumulative effect, which suggests these herbicides do not present a substantial hazard to aquatic or terrestrial wildlife.

The basic physical chemical and other properties of the DPhE herbicides are listed in Tables 20–22.

6.2 Analytical Method for Diphenyl Ether Analysis

6.2.1 Extraction

The extractive methods for DPhEs from environmental and food samples are given in Table 23.

LLE is the method chosen by several authors[37,84,85] for DPhE extraction from aqueous samples. In some work[37,84] the sample is shaken with an immiscible organic solvent such as dichloromethane; Edgell et al.[85] extracted acifluorfen at pH < 2 with ethyl ether.

Sorption on to a solid sorbent provides a useful method for the isolation of DPhEs from aqueous samples. The most common sorbent used in SPE is C_{18} bonded silica cartridges.[39,41,43,45,86–88]

Junker-Buchheit and Witzenbacher[89] have developed an alternative SPE sorbent material to extract bifenox from tap water. This adsorbent is based on a highly cross-linked, porous ethylvinylbenzene–DVB copolymer and exhibits a unique adsorption efficiency due to its high specific surface area. The ability of this adsorbent (LiChrolut EN) is comparable to a conventional RP-18 solid phase. Increased attention has been devoted to carbon sorbents,[87,90] in addition to those with an SiO_2 matrix. GCB is a nonspecific sorbent and is generally hydrophobic. Contrary to the sorbents based on SiO_2, this may be used without taking into account the pH of the treated solutions.

Comparisons of different sorbents for SPE are proposed. SPE materials and techniques (C_{18} Empore disks, polystyrenedivinylbenzene, C_{18} Bond Elut cartridges, and ENVI-Carb cartridges) have been compared for the extraction of bifenox from water.[87] Hodgeson et al.[91] evaluated C_{18} and polystyrene DVB resin disks for the extraction of DPhEs in aqueous samples. Fibers coated with PDMS or liquid crystals of PAC have been developed for the extraction of oxyfluorfen from water samples[92] by SPME. SPME is an alternative technique that involves direct extraction of the analyte with the use of a small diameter optical fiber that has been coated with a polymeric stationary phase and housed in a syringe assembly for protection. SPME eliminates the separate concentration step from the SPE and LLE methods because the analytes diffuse directly into the coating of the SPME device and are concentrated there. XAD-2 has been utilized for the extraction of bifenox from river water.[93]

DPhE residues in soil and food samples are traditionally extracted from the solvent with some physical assistance (sonication, shaking, homogenizing). The solvents used include acetone,[51,53,94,95] acetonitrile,[67,96] mixed methanol–water (3 : 1, v/v),[62] dichloromethane–ethanol–acetone (6 : 2 : 1, v/v),[97] and methanol–0.1 mol L^{-1} NaOH (80 : 20, v/v).[98]

Homogeneous sample pulp containing oxyfluorfen, prepared from fruit and vegetables of different water content with or without additional water, is adsorbed on the surface of activated Florisil to obtain a free-falling powder, which is extracted in a glass column with ethyl acetate or dichloromethane–acetone (9 : 1, v/v).[59]

6.2.2 Cleanup

The choice of cleanup technique closely depends on how the extraction was done; in other words, whatever else enters the extract determines the purification procedure.

Uses[b]	U1	U2	U3		U4	U5	U6	U7

[a] WHO toxicity class: Ia, extremely hazardous; Ib, highly hazardous; II, moderately hazardous; III, slightly hazardous.

[b] U1 = PoE control of annual broad-leaved weeds (*Abutilon, Amaranthus, Datura, Euphorbia, Poligonum, Ipomea, Xanthium*) with some effects on grasses in soybeans, peanuts and rice; U2 = PrE control of grass, and broad-leaved weeds in winter wheat, potatoes, sunflowers, peas, carrots, maize and other crops; U3 = PrE and PoE control of annual broad-leaved weeds and some grasses in cereals, sorghum, soybeans, rice, and some other crops; U4 = PrE and PoE control of broad-leaved weeds and grasses, particularly *Gallium, Viola* and *Veronica*, in wheat, balley, oats, peanuts, rice, and soybeans; U5 = early PoE control of broad-leaves weeds in soybeans; U6 = PoE control of annual broad-leaved weeds in cereals, potatoes, soybeans, rice and peanuts; U7 = PrE and PoE control of annual broad-leaved weeds and grasses in a variety of tropical and subtropical crops, particularly in tree fruit, including citrus, vines, nuts, cereals, maize, soybeans, peanuts, rice, cotton, bananas, peppermints, onions, garlic, ornamental trees, and shrubs, and conifer seedbeds.

Table 23 Extraction and cleanup procedures used in the determination of DPhE herbicides

Compound	Matrix	Extraction	Partition step	Cleanup	Ref.
Oxyfluorfen	soil	sonication with water and methanol (1 : 3, v/v)	–	SPE C_{18} disk	62
Acifluorfen	water	Carbograph-1	–	–	90
Bifenox	tap water	LiChrolut EN or LiChrolut RP-18 cartridge	–	–	89
Oxyfluorfen	water	SPE C_{18}	–	–	86
Oxyfluorfen	water	SPME/PAC or SPME/PDMS	–	–	92
Acifluorfen	groundwater	dichloromethane	–	–	37
Bifenox	water	SPE C_{18} or Empore C_{18} disks or SPE-Envi-Carb	–	–	87
Oxyfluorfen	water	dichloromethane	hexane	–	84
Acifluorfen	drinking water, groundwater	SPE C_{18}	–	–	39
Acifluorfen	tap water, groundwater	SPE C_{18}	–	–	41
Fluoroglycofen Bifenox	fruit and vegetable matrices	acetone	petroleum ether and dichloromethane	–	51
Acifluorfen	drinking water, surface water, sewage water	SPE C_{18}	–	–	43
Acifluorfen	drinking water	pH < 2 with ethyl ether	–	–	85
Acifluorfen	reagent water, tap water, surface water, groundwater	Empore C_{18} and PS/DVB disks	–	–	91
Bifenox	vegetables	acetone	dichloromethane	GPC (Bio-Beads-X3)	94
Chlornitrofen	river water	SPE C_{18}	–	–	88
Oxyfluorfen	fruit and vegetables	Florisil	–	–	59
Bifenox	soil	dichloromethane–ethanol–acetone (6 : 2 : 1, v/v/v)	–	GPC (Bio-Beads S-X3)	97
Bifenox Oxyfluorfen	fruit and vegetables	acetonitrile	–	–	67
Bifenox	agricultural products	acetone	–	GPC (Bio-Beads S-X3)	53
Fomesafen	groundwater	SPE C_{18}	–	–	45
Bifenox	agricultural products	acetone	hexane	GPC (Bio-Beads S-X3)	95
Bifenox Oxyfluorfen	crops	acetonitrile	–	Attagel, Florisil, SPE C_{18}	96
Acifluorfen	soil, water	methanol–0.1 M NaOH (80 : 20, v/v)	dichloromethane	Sep-Pac silica cartridge	98
Bifenox	river water	XAD-2	–	–	93

PAC, polyacrylate; PDMS, polydimethylsiloxane; XAD-2, styrene–divinylbenzene copolymer.

LLP followed by column chromatography or SPE has been the most common cleanup procedure in DPhE analysis. Dichloromethane,[94,98] hexane,[84,95] and petroleum ether and dichloromethane[51] are used in LLP. Hsu et al.[96] have investigated the potential of a SPE cartridge, Florisil, and SPE-C_{18}, to replace Attagel in the bifenox cleanup procedure for raw agricultural crops. SPE with a silica cartridge was used by Gennari et al.[98] for the cleanup of the organic extracts of soil and water in acifluorfen determination. An alternative mode of SPE is the use of the ''SPE disks''. Bao et al.[62] reported the use of C_{18} Empore extraction disks for isolation and cleanup of oxyfluorfen in soil.

The most universally applicable cleanup of organic extracts of DPhE from soil,[97] vegetables,[94] and agricultural products[53,95] is GPC. Separation is generally performed by using DVB-linked polystyrene gels, mostly Bio Beads SX-3. For the elution of DPhE herbicides, the mixtures cyclohexane–EtOAc (50 : 50, v/v) and cyclohexane–acetone (50 : 50, v/v) are used.

6.3 Determination

Once the sample has been extracted from its matrix, usually into a suitable solvent, it is then ready to be analyzed by the appropriate technique. Chromatographic methods, and in particular GC and HPLC, are the methods of choice. GC is often the first choice in the analysis of DPhEs because of their good response with ECD; however, DPhEs are also well analyzed by HPLC, and this

is often used in conjunction with UV detection. GC or HPLC, coupled with MS, provides the analyst with a powerful tool for both determination and confirmatory analysis. Because of the good voltammetric behavior of fluoroglycofen, the mercury-drop electrode is also applied.

6.3.1 Gas Chromatography

Fused capillary columns with phases of different polarity have been used: (nonpolar examples are SBP-5,[90] 5% phenylmethylsilicone,[86] DB-5,[59,84,91] 5% phenyl–95% methylpolysiloxane;[85] low-polar examples are 65% dimethyl–35% diphenylpolysiloxane,[37] SBP-608,[41] 50% phenyl–50% methylsilicone,[96] OV-17.[93]); typical dimensions are IDs of 0.22–0.53 mm, film thicknesses of 0.25–1 μm, and lengths of 12.5–60 m.

Figure 10 Chromatograms by (a) HPLC/UV and (b) GC/ECD separation of pesticides extracted from 1 L spiked water. (Reproduced by permission of Vieweg from F. Bruner, A. Berloni, P. Palma, *Chromatographia*, **43**, 279–284 (1996).)

Some derivatization methods have been developed to improve the sensitivity and the peak-tailing situation in the case of acifluorfen and fluoroglycofen. The most used derivatization procedures are with diazomethane,[85,90,91] 2,2,2-TFE,[37] pentafluorobenzyl bromide,[39,43] and methyl, ethyl, and butyl chloroformate.[41] As all DPhEs bear a chlorine heteroatom, the most used detection system is ECD.[37,41,59,85,86,90,91,93,96] Oxyfluorfen in water[86] is determined by GC with ECD and flame photometric detection (FPD). A GC/AED system[84] is used to analyze nitrogen-containing oxyfluorfen herbicides. The use of GC linked to AED offers an alternative to GC/MS for unambiguous determination of unknowns. The coupling technique was shown to be a very selective tool with element-characteristic chromatograms acquired using different element emission lines, thereby enhancing the selectivity of the method for environmental monitoring.

Figure 10 illustrates chromatograms by HPLC/UV and GC/ECD of a water sample spiked with acifluorfen.

Table 24 summarizes the column, mobile phase, detector, and DLs currently employed in routine DPhE residue analysis.

6.3.2 High-performance Liquid Chromatography

The usual way to obtain a good separation of acidic DPhE in GC is by chemical derivatization. HPLC is the method of choice for ionic compounds, acifluorfen, fluoroglycofen, fomesafen, and bifenox acid, which are not amenable to GC.

An RP/HPLC column containing C_{18} bonded silica sorbent[45,87,89,90,97–99] is used for analytical separation. Narrow-bore (3 mm ID) columns and 3 μm particles[87,99] have been applied in recent studies. For the elution, a mixture of acetonitrile and aqueous solution is used in isocratic mode.[45,97–99] Gradient elution with acetonitrile and water modified with TFA[90] or ammonium acetate[87,89] have also been utilized. Buffer solutions with the pH-adjusted to below the pK_a values of the acidic DPhE are prepared from TFA,[90] H_3PO_4,[97,98] and CH_3COOH.[45]

UV detection, in the range 206–296 nm, is the most popular detection method in the analysis of DPhE residues.[45,87,90,97–99] In the determination of bifenox from tap water[89] an increase of confirmation ability has been achieved with DAD technology. Zhou and Miles[99] have demonstrated that oxyfluorfen can be determined selectively in crops by PCD. PCD and UV liquid chromatographic detectors also are evaluated.

The analytical conditions for HPLC analysis are presented in Table 25. Figure 11 shows a chromatogram of a soil extract of bifenox and its main metabolite, bifenox acid, using an UV detector.

Table 24 Gas chromatographic determination of DPhE herbicides

Compound	Matrix	Column, dimension, temperature	Detector	DL	Ref.
Acifluorfen	water	SBP-5, 30 m × 0.25 mm ID, 60–300 °C	ECD	0.08 ng L^{-1}	90
Oxyfluorfen	water	ultra two-capillary column 5% phenylmethylsilicone, 25 m × 0.32 mm ID, 160–280 °C; HP-1 methylsilicone, 12.5 m × 0.22 mm ID, 45–270 °C	ECD, FPD	22 ng L^{-1}	86
Acifluorfen	groundwater	cross-bonded 65% dimethyl–35% diphenyl polysiloxane, 30 m × 0.53 mm ID, 130–260 °C	ECD	1000 ng L^{-1}	37
Oxyfluorfen	water	DB-5, 30 m × 0.32 mm ID, 75–320 °C	AED	0.22 ng L^{-1}	84
Acifluorfen	tap water, groundwater	SBP-608, 30 m × 0.25 mm ID, 50–280 °C	ECD	<100 ng L^{-1}	41
Acifluorfen	drinking water	5% phenyl–95% methylpolysiloxane, 30 m × 0.25 mm ID, 60–300 °C	ECD	–	85
Acifluorfen	reagent water, tap water, surface water, groundwater	DB-5, 30 m × 0.25 mm ID, 50–230 °C	ECD	250 ng L^{-1}	91
Oxyfluorfen	fruit and vegetables	DB-5, 60 m × 0.245 mm ID, 85–300 °C	ECD	10 ng g^{-1}	59
Bifenox Oxyfluorfen	crops	50% phenyl–50% methyl silicone, 15 m × 0.25 mm ID, 170–240 °C	ECD	–	96
Bifenox	river water	OV-17 CB-FSC, 25 m × 0.32 mm ID, 90–275 °C	ECD	5 ng L^{-1}	93

Table 25 HPLC Determination of DPhE herbicides

Compound	Matrix	Column	Mobile phase	Detector	Wavelength (nm)	DL	Ref.
Acifluorfen	water	C_{18} RP	solvent A: H_2O + 0.05% TFA solvent B: CH_3CN + 0.025% TFA gradient	UV	280	41.7 ng L^{-1}	90
Bifenox	tap water	LiChroCART 250–4, Superspher 100, RP-18	solvent A: ammonium acetate solvent B: CH_3CN gradient	DAD/UV	220	7000 ng L^{-1}	89
Bifenox	water	Hypersil ODS, 3 µm	solvent A: ammonium acetate solvent B: CH_3CN gradient	UV	220	61–147 ng L^{-1}	87
Bifenox Bifenox acid	soil	Hypersil ODS	CH_3CN–0.05 mol L^{-1} H_3PO_4 (65:35, v/v)	UV	206	4 ng g^{-1}	97
Fomesafen	groundwater	Ultrasphere ODS	CH_3CN–H_2O (50:50 v/v) + 0.4% acetic acid	UV	270	100 ng L^{-1}	45
Oxyfluorfen	Carbanzo beans	HS–C_{18}, 3 µm or OmiPac PAX-500	CH_3CN–H_2O (58:42, v/v); 1.8 mmol L^{-1} Na_2CO_3 and 1.7 mmol L^{-1} $NaHCO_3$	UV, PCD	277	<200 ng g^{-1}	99
Acifluorfen	soil, water	LiChrosorb RP-18	H_2O (pH 3 with H_3PO_4)–CH_3CN (30:70, v/v)	UV	296	6 ng g^{-1} 3 ng g^{-1}	98

6.3.3 Hyphenated Techniques

Although GC and HPLC are widely accepted for the residual analysis of DPhE, the need for compound identification cannot be overemphasized. This is particularly necessary for soil and agricultural products in which peak overlapping or unresolved peaks originating from matrix interference exist.

Table 26 summarizes the characteristics and the DLs of hyphenated techniques used for DPhE herbicide determination and confirmation in environmental and food samples.

GC/MS has become the preferred analytical technique. DPhE herbicides have been determined by GC/MS directly or after the preparation of derivatives.

Figure 11 HPLC chromatogram for bifenox and bifenox acid in soil extract with cleanup; fortification level 0.1 mg kg^{-1}. (Reproduced from *Fresenius' J. Anal. Chem.*, 'Simultaneous Determination of the Herbicides Isoproturon, Dichlorprop-p and Bifenox in Soil Using RP/HPLC', H. Klöppel, J. Haider, C. Hoffmann, B. Lüttecke, **344**, 42–46, Figure 3, 1992, Copyright Springer-Verlag.)

GC/MS in EI mode in TIC was used for monitoring oxyfluorfen,[92] and acifluorfen[41] in water samples, bifenox and oxyfluorfen[67] and bifenox[53] in agricultural products. Capillary GC with MSD employing SIM with time window programming were developed for acifluorfen,[39,43] and chlornitrofen[88] in drinking water and surface water.

GC/MS of DPhE residue analysis has been largely restricted to quadrupole instruments. Another technique that has been used for DPhE quantitation is that of GC/IT/MS. The components of an IT system are much less complicated than the instrumentation previously mentioned and rely on electronic control to obtain mass spectra. Bao et al.[62] utilized IT/MS for testing oxyfluorfen in soil. The same technique was used by Cairns et al.,[51] and Tuinstra et al.[94,95] for bifenox and fluoroglycofen determination in agricultural products.

One potential approach to the determination of acifluorfen in water[90] is the use of HPLC/MS in conjunction with interface particle-beam. In this work, to improve the sensitivity, the PB target zone inside the ion source is coated with a Teflon layer. It is well known that when acidic pesticides enter the ion source, they undergo decomposition due to the high temperature of the ionization chamber (>200 °C). This inconveniently causes a reduction in sensitivity and an unwanted memory effect. Coating the ion source reduces adsorption and decomposition, and enhances the gas-phase conversion of analytes.

6.3.4 Other Techniques

Classical DC polarography and fast-scan differential pulse voltammetry were applied to study the reduction mechanism of fluoroglycofen-ethyl at a dropping mercury electrode (DME) and at a static mercury-drop electrode

Table 26 Determination of DPhE herbicides using hyphenated techniques

Compound	Matrix	Technique	MS conditions	DL	Ref.
Oxyfluorfen	soil	GC/MS	IT	4 ng g^{-1}	62
Acifluorfen	water	LC/PBMS	SIM	5.2 ng L^{-1}	90
Oxyfluorfen	water	GC/MS	EI, TIC	1 ng L^{-1}	92
Acifluorfen	drinking water, groundwater	GC/MS	EI, SIM	≤10 ng L^{-1}	39
Acifluorfen	tap water, groundwater	GC/MS	EI, TIC	<100 ng L^{-1}	41
Bifenox Fluoroglycofen	fruit and vegetables	GC/MS	IT	sub-μg g^{-1} level	51
Acifluorfen	drinking water, surface water, sewage water	GC/MS	EI, SIM	10 ng L^{-1}	43
Bifenox	vegetables	GC/MS	IT	50 ng g^{-1}	94
Chlornitrofen	river water	GC/MS	EI, SIM	50 ng L^{-1}	88
Bifenox Oxyfluorfen	fruit and vegetables	GC/MS	EI, TIC	150 μg g^{-1} 50 μg g^{-1}	67
Bifenox	agricultural products	GC/MS	EI, TIC	below 250 ng g^{-1}	53
Bifenox	agricultural products	GC/MS	IT, TIC	–	95

Figure 12 GC/MS reconstructed ion chromatogram of a combined endive, cucumber, and cauliflower extract spiked with pesticides (full-scan mode). (Reprinted from *J. Chromatogr.*, **552**, L.G.M.Th. Tuinstra, F.R. Povel, A.H. Roos, 'Multi-matrix Multi-pesticide Method for Agricultural Products', 259–264, Copyright 1991, with permission from Elsevier Science.)

(SMDE) in a medium of 47–49% (v/v) or 10–20% (v/v) dimethylformamide.[100] The nitro groups were reduced to hydroxylamine derivatives, or further to the corresponding amines, depending on the type of compound and the solution acidity. The determination of nitropesticide was performed using FSDVP and adsorptive stripping voltammetry (AdSV) in model samples. The DLs were found both experimentally and by calculation from regression analyses. According to the experimental condition their values were in the range 17–160 ng mL^{-1} or 0.1–2.8 ng mL^{-1} for FSDVP or AdSV, respectively. The nitropesticide in artificially contaminated soils was determined after two or three extractions with acetone.

Figure 12 shows a reconstructed ion chromatogram of an extract of crops spiked with bifenox. Selected-ion chromatograms of standards, blind, and recovery river water samples showing the ion trace for each selected masses are presented in Figure 13.

The important role of high-performance liquid chromatography (HPLC) in pesticide residue analysis (PRA) is presented. Based on the experience and view of the author, a number of reliable and robust liquid chromatography (LC) approaches and methods have been selected to highlight the favorable features of this technique in this field of analysis.

Reversed-phase liquid chromatography (RPLC) with ultraviolet (UV) detection mode is most widely adopted, owing to its ability to perform efficient separation of very polar to apolar pesticides and the universal character of the detection mode. Therefore, a large part will deal with reversed-phase liquid chromatography/ultraviolet (RPLC/UV) applications showing its excellent separation performance and detectability of compounds not directly amenable to gas chromatography (GC).

Another important feature of RPLC is the possibility of including sample pretreatment steps such as sample concentration and/or cleanup in the analytical procedure. The very good compatibility with aqueous samples or extracts easily permits RPLC on-line sample loading (trace enrichment) by means of column switching, allowing fully automated procedures. It will be shown that, depending on whether the first column is a low- or a high-resolution column, two different modes of column switching, solid-phase extraction (SPE) to LC and LC to LC, are adopted in the determination of pesticides. The type of columns and materials, the advantages and the application range of both column-switching modes is discussed in detail. Attention will be paid to method development including both the straightforward trial-and-error approach and more systematic method development procedures.

The more selective/sensitive detection modes, fluorescence detection (FD) and mass spectrometry (MS) as applied in pesticides residue analysis will be discussed with emphasis on the increasing importance of MS for identification and quantification of polar pesticides in various types of samples.

Finally, the use of LC methods involving normal-phase liquid chromatography (NPLC), low-resolution RPLC and gel permeation chromatography (GPC), will demonstrate the powerful sample pretreatment feature of LC prior to gas chromatographic analysis.

1 INTRODUCTION

The major task of the analytical discipline PRA is to provide reliable and, moreover, cost-effective methods for the identification and quantification of hundreds of pesticides with large differences in physicochemical properties in very different types of matrices. The introduction of high-resolution capillary GC employing fused silica columns in the early 1980s, combined with the commercial availability of several sensitive and, moreover, selective GC detectors, contributed greatly to the rapidly increasing popularity of GC-based procedures for PRA. These favorable aspects make capillary GC, today, the major analytical and productive technique for this type of analysis. For example, in the Netherlands a multiresidue method (MRM) based on GC with MS detection used for regulatory purposes[1] covers the determination of 270 pesticides in foodstuffs from a total of 465 mentioned in the Dutch Regulation on Pesticides in Foodstuffs.[2] An overview of most pesticides which are not covered by the gas chromatography/mass spectrometry (GC/MS) method is given in Table 1. These pesticides and their corresponding chemical families are characterized by low volatility, high polarity and/or thermal instability making them not directly amenable for GC. For this type of analyte LC can be a good alternative. Most of these analytes can be nicely separated and efficiently detected by means of RPLC with UV detection, while GC analysis requires an often complicated derivatization procedure prior to separation. The availability of robust and more selective fluorescence and mass spectrometric detectors for LC further enhances the practical value of this separation technique.

It must be stressed that, because it is possible to combine high sensitivity and selectivity (confirmation), GC/MS procedures involving a derivatization step are still attractive and frequently applied for the thermostable compounds such as phenoxy acids. In fact, one must emphasize the complementary aspect of LC to GC. For example, LC can be a more viable way for the determination of thermolabile compounds such as carbamates or analytes difficult to derivatize, such as quaternary ammonium compounds.

Beside the advantageous use of HPLC for (very) polar pesticides, there are, as displayed in Figure 1, other important considerations for selecting HPLC in PRA. For example, in monitoring and/or indicative studies rendering a relatively low number of positive samples, the availability of a screening method(s), e.g. RPLC/UV for the determination of polar pesticides, can be cost-effective. The ability of RPLC to separate apolar and very polar analytes in one run makes it possible to determine pesticides simultaneously with their usually distinctly more polar metabolites.

RPLC is very compatible with aqueous samples, which enables sample pretreatment steps to be included by means of column switching in the analytical procedure, allowing fully automated (on-line) methods for the determination of pesticides in water samples. Furthermore, direct injection of a large volume of water makes RPLC attractive for other types of study, e.g. to study the formation of metabolites and transformation products (TPs) of pesticides at real-life trace levels (in-line analysis) or the at-site monitoring of pesticides in suspected water locations.

Other LC modes like GPC or NPLC have proven to be efficient for the cleanup of difficult matrices, e.g. fatty food products or soils. The high potential for automation provides semi and/or fully automated procedures effectively replacing the conventional laborious and less accurate open-column LC procedures.

Concerning methodology one can discriminate between single residue methods (SRMs) and MRMs. From an economical point of view, MRMs are highly desirable because the detection and quantitative determination of a series of pesticides in one run considerably reduces the cost of analysis.

However, multiresidue analysis of pesticides is faced with several problems. Firstly PRA has to cover the two disciplines including public health and environmental protection. Consequently, one has to deal with a large variety of sample types of widely diverging composition making it difficult to include the multimatrix aspect into an MRM. There is no guarantee that a method developed, for example, for the determination of chlorophenoxy acids in soils, will work for some foodstuffs, so different MRMs are required for the same group of pesticides.

Another difficulty is caused by regulations in relation to the different matrices. For example, maximum residue levels (MRLs) of pesticides in foodstuffs arranged by the Dutch legislation[2] are in agreement with the directives of the European Community (EC) and comply with the recommendations of the Codex Committee on Pesticide Residues (CCPR). These levels are based on scientific evaluations estimating the acceptable daily intake and the expected residue level in food when a pesticide is used according to good agricultural practice. As a result, for a single pesticide MRL ranges can be encountered which comprise several orders of magnitude posing a severe problem in multiresidue analysis. For most environmental samples and drinking water, the MRLs are generally much lower than for food samples. The EC directive for drinking water[3] states that the concentration of pesticides and related products should not exceed the level of $0.1\,\mu g\,L^{-1}$ (ppb) for individual compounds and $0.5\,\mu g\,L^{-1}$ for total pesticides. This essentially means that methods of analysis are required which are about 1000 times more sensitive than those for foodstuffs.

Table 1 Overview of pesticides not amenable to GC[a]

Pesticide	Chemical family	Pesticide	Chemical family
Abamectin	antibiotic	Fenoxaprop-ethyl	acid, phenoxy
Aclonifen	phenoxyaniline	Fenoxaprop-P-ethyl	acid, phenoxy
Aldicarb	carbamoyloxime	Fentin acetate	organotin
Amitraz	amidine	Fentin hydroxide	organotin
Amitrole	triazole	Fenuron	urea, phenyl
Azaconazole	triazole	Fluometuron	urea, phenyl
Benazolin	benzothiazole	Formetanate	carbamate
Bendiocarb	carbamate	Glufosinate	acid, phosphinic
Benomyl	benzimidazole	Glyphosate	acid, phosphinic
Bentazone	benzothiadiazole	Ioxynil	nitrile;
Benzthiazuron	urea, phenyl	Isoprocarb	carbamate
Bromoxynil	nitrile,	Isoproturon	urea, phenyl
Butocarboxim	carbamoyloxime	Linuron	urea, phenyl
Butoxycarboxim	carbamoyloxime	Maleic hydrazide	pyridazine
Carbaryl	carbamate	MCPA	acid, phenoxy
Carbendazim	benzimidazole	MCPB	acid, phenoxy
Carbetamide	carbamate	MCPP	acid, phenoxy
Carbofuran	carbamate	Mepiquat chloride	quaternary ammonium
Chlorbufam	carbamate	Metamitron	triazine
Chloridazon	pyridazinone	Methabenzthiazuron	urea, phenyl
Chlormequat	quaternary ammonium	Methiocarb	carbamate
Chlorobromuron	urea, phenyl	Methomyl	carbamate
Chlorotoluron	urea, phenyl	Metobromuron	urea, phenyl
Chloroxuron	urea, phenyl	Metoxuron	urea, phenyl
Chlorpropham	carbamate	Metribuzin	triazine
Chlorsulfuron	urea; sulfonyl	Metsulfuron-methyl	urea, sulfonyl
Chlorthiamid	thiobenzamide	Monolinuron	urea, phenyl
Cloethocarb	carbamate	Monuron	urea, phenyl
2,4-D	acid, phenoxy	Natamycin	antibiotic
2,4-DB	acid, phenoxy	Neburon	urea, phenyl
Desmedipham	carbamate	Oxamyl	carbamoyloxime
Dicamba	acid, benzoic	Paraquat	quaternary ammonium
2,4-DP	acid, phenoxy	Phenmedipham	carbamate
Dicloran	aniline (nitro-)	Promecarb	carbamate
Difenoxuron	urea, phenyl	Propamocarb	carbamate
Difenzoquat	quaternary ammonium	Propoxur	carbamate
Diflubenzuron	urea, phenyl	Pyridate	pyridazine
Dimethomorph	acid, cinnamic	Quinmerac	quinoline
Dinoseb	dinitrophenol	Rimsulfuron	urea, sulfonyl
Dinoseb-acetate	dinitrophenol	Rotenone	rotenoid
Dinoterb	dinitrophenol	Streptomycin	antibiotic
Dioxacarb	carbamate	2,4,5-T	acid, phenoxy
Diquat	quaternary ammonium	Teflubenzuron	urea, phenyl
Dithiocarb	carbamate	Thiabendazole	benzimidazole
Diuron	urea, phenyl	Thifensulfuron-methyl	urea, sulfonyl

[a] Data from van Zoonen.[1]

Figure 1 The involvement of HPLC in PRA.

Thus for the same group of compounds, different MRMs for different matrices and corresponding MRLs are sometimes encountered in literature.

The large variety of physico-chemical properties such as polarity, volatility, thermostability and, occasionally, molecular weight of the pesticides makes the simultaneous chromatographic separation and detection more difficult and counteracts the availability of MRMs.

Because of productivity most attention will be given to MRMs. However, the availability of fast SRMs can be attractive in this field of analysis. Especially, in survey programs based on use patterns and ad hoc requests for a certain pesticide/matrix combination, screening methods are efficient. For this type of analysis it is even better to have efficient method development strategies available.

Not all methods that have been published can be included and, hence, a comprehensive overview is not given. For such information, excellent textbooks reviewing the LC analysis of pesticides residues in foodstuffs[4] and environmental[5] samples are available.

Here, the versatility and feasibility of LC in PRA is demonstrated by making a careful selection of various types of current state methodologies encountered in PRA. After a general section on the LC analysis of pesticides, the further content is based on different LC modes. Within these modes further discrimination will be made as regards analytes and matrices.

2 REVERSED-PHASE LIQUID CHROMATOGRAPHY WITH ULTRAVIOLET DETECTION

2.1 General Aspects

RPLC is a suitable technique for the determination of polar analytes in water, since derivatization is usually superfluous and in the analysis of aqueous samples the mobile-phase system is fully compatible permitting automation of the analytical procedure. The wide application range, long-term stability, ease of use, low cost and improved selectivity (diode array) means that the combination of UV detection and RPLC is still widely used in residue analysis.

Figure 2 Performance of RPLC/UV (236 nm). Injection of 200 µL of standard carbamate pesticides in water–methanol (10 : 90, v/v) on a 100 × 4.6 mm internal diameter (ID) column packed with 3 µm Microspher C_{18}. Mobile phase, methanol–water (55 : 45, v/v) at a flow of 1 mL min^{-1}. Injected amount, about 10 ng of each pesticide on column.

The chromatogram displayed in Figure 2 nicely illustrates RPLC performance. Employing an injection volume of 200 µL, an efficient elution and separation of eight carbamate pesticides is obtained in less than 10 min employing a 100 × 4.6 mm column packed with 3 µm C_{18}, and an isocratic elution. The chromatogram of Figure 2 also shows limitations. Under these conditions the number of peaks that can be separated in one run is limited, increase of separation power by extending the length of the column will be restricted by column pressure, and the longer retention time inversely affects sensitivity, as shown in the chromatogram of Figure 2. Gradient elution enhances the total number of peaks that can be separated in one run and effectively controls band broadening of analytes. However, a severe baseline drifting usually occurs in the trace analysis employing nonselective UV detection at low wavelengths.

The problems usually encountered in RPLC/UV analyses of residues of pesticides in samples and extracts is shown by the simulated chromatogram in Figure 3. The most common problem is caused by abundantly present early eluting sample constituents indicated as S1. In many cases S1 can be largely removed via low-resolution cleanup such as off-line SPE or on-line with solid-phase

Figure 3 Simulated chromatogram of sample interferences occurring in the RPLC/UV trace analyses of pesticides. S1, S2 and S3, sample interferences; A1, A2 and A3, analytes.

extraction/liquid chromatography (SPE/LC). However, in the case of analytes with a polarity close to the range of the large excess of interfering constituents such a cleanup will not be sufficient.

Compounds with longer retention times than the analytes, S3, do not really interfere, but cause an unfavorable increase of the time of analysis. Tuning the selectivity by small changes in mobile-phase compositions, e.g. eluotropic strength or type of modifier, is usually applied to improve the separation caused by interferences of type S2.

The high compatibility between mobile phases and aqueous samples and extracts, and convenient instrumental operation provide an important feature of RPLC, that is, column switching. The use of more then one column offers the possibility to perform on-line sampling and/or cleanup which enhance sample throughput, sensitivity and/or selectivity in a cost-effective way.

In most cases, the sample preparation step is performed on a small precolumn (PC) installed in a column-switching system which permits the analytes to be desorbed automatically, after sample loading and a washing step, to the analytical LC column for separation and detection. Until the early 1990s this technique was usually named precolumn/liquid chromatography (PC/LC). Nowadays (and also here) the term SPE/LC is used for the various types of system using PCs, disposable cartridges and/or solid-phase extraction disks (SPEDs) coupled on-line to the analytical column.

In SPE/LC, PCs with dimensions of, typically, 5–10 mm (L) × 2–4.6 mm ID are usually employed. In order to enable fast sampling, PCs are packed in most instances with 10–40 μm material. The small size reduces cost, and favors a fast desorption to the analytical column. A typical setup of a fully automated solid-phase extraction/liquid chromatography/diode array detection (SPE/LC/DAD) system is shown in Figure 4. This SPE/LC set-up is called SAMOS (System for Automated Monitoring of Organic Compounds in Surface Water) and was specially developed as an early warning system for the pollution control of surface waters.[6,7]

It will be obvious that hydrophobic type SPE/LC is a highly efficient trace-enrichment procedure, but does not contribute much to increase selectivity. For the determination of some specific groups of pesticides, sorbents with a different retention mechanism such as ion exchange have been successfully applied to improve selectivity in SPE/LC.[8]

Coupled column reversed-phase liquid chromatography (LC/LC) employing a full size separation C_{18} column as the first column (C-1) is a good alternative to improve selectivity in hydrophobic column switching.[9–11] This

is illustrated in Figure 5 which schematically shows the important steps involved in the heart-cutting technique. As well as using the separation power of the first column (C-1) to remove effectively interferences of types S1 and S3, this approach acts as an analyzer. The high sample throughput of LC/LC originates from the fact that sample injection is performed in the high-pressure mode by an autosampler equipped with a large volume loop and a syringe pump. The insertion by the injector of an air gap in front of and after the sample provides fast and accurate LVI with a minimal consumption of sample. This feature allows the use of rather small autosampler vials and facilitates the processing of large series of samples.

The major advantage of LC/LC is the high resolution of C-1, which contributes to the enhancement of the selectivity by removing a large part of the early eluting interferences, S1. Another crucial feature of LC/LC is the transfer volume, or the time that C-1 is coupled on-line to C-2. Obviously, the size of the transfer volume (A) will be inversely proportional to selectivity, making LC/LC most powerful in single-residue analysis. However, the key to success in the enhancement of the selectivity in the analysis of polar analytes, especially in environmental samples, is the effective removal of early eluting interferences. Therefore, the development of MRMs involving larger transfer volumes, which would lead to less selectivity, can still be quite attractive.

Starting with RPLC/UV method development for successful applications in trace analysis of pesticides, methods will be discussed highlighting the possibilities, features and limitations of RPLC, SPE/LC and LC/LC with or without off-line sample pretreatment procedures.

Next, LC methods in combination with more selective detection, FD and MS detection, will be discussed. Finally, with emphasis on cleanup, other types of LC applications will be presented.

2.2 Practical Method Development

The discussion of the important RPLC/UV parameters will be done by following the scheme of Figure 6 which is based on the author's experience, and used in LC and LC/LC methods developed for the determination of polar pesticides in environmental samples.[9–11]

The possibility of an RPLC/UV method is determined by the applicable UV absorption (wavelength, λ (nm) and molar extinction coefficient, ε ($L\,mol^{-1}\,cm^{-1}$)) and the retention (capacity factor, k) of the analyte(s) from pure water onto the C_{18}-type stationary phase. With insufficient

Figure 6 Scheme of straightforward LC- and LC/LC/UV method development in PRA.

ultraviolet/visible (UV/VIS) absorption/selectivity (ε values of less than ca. $1000\,\mathrm{L\,mol^{-1}cm^{-1}}$ and $\lambda < 200\,\mathrm{nm}$) and/or an essential absence of retention on a C_{18}-bonded phase (k values of less than ca. 1), the successful development of an RPLC/UV procedure for trace level analysis becomes highly unlikely.

RPLC/UV information on pesticides acquired at our laboratory is given in Table 2. In this Table the UV absorption maximum was selected as a good compromise between selectivity and sensitivity as encountered in this field of analysis. Beside UV sensitivity (ε), the peak elution volume of the analyte inversely contributes to the degree of analyte detectability. Therefore, information on the elution of the analyte, expressed as the column efficiency (N), is included in Table 2. The large difference in efficiency ranging from 280 (cypermethrin) to 5100 (chlorbufan) clearly emphasizes the importance of this parameter to sensitivity.

Table 2 RPLC/UV information on pesticides[a]

Pesticide	Modifier (%)	k	N[b]	λ(nm)	ε_0(L mol^{-1} cm^{-1})

As indicated in Figure 6 the next step is to select adequate RPLC parameters concerning separation power and elution conditions. These parameters are determined by the dimension of the column (LC) or columns (LC/LC) and the mobile phases (M). It must be stressed that, from an efficiency point of view, one should not optimize the method beyond a certain degree: the LC system must be kept as simple as possible. For example, if sample extracts are clean enough, column-switching can be omitted. However, trace analysis requires in most cases an efficient cleanup of sample or extract.

For the on-line cleanup, C-1 must provide sufficient separation to remove a major part of the abundantly available early eluting matrix constituents, S1, prior to elution of the analyte. Therefore a column with high separation power is attractive. However, an unnecessary increase of separation power and dimension of the column must be avoided; the peak elution volume, which is inversely proportional to the sensitivity in detection of the analyte, should be kept as low as possible. An increase of the column dimension will also increase the reconditioning time (if necessary) of C-1 between analyses. In general, an eluotropic strength of M-1 should be selected such that the capacity factor of the analyte is in the range of $1 < k' < 5$, yielding a cleanup volume of at least two times the dead volume of the column (V_0) to remove a large part of the excess of early eluting interferences.

Especially in the analysis of compounds with little C_{18} retention, it is favorable to select a second column (C-2) with a higher separation power than C-1. This will provide some flexibility when optimizing the eluotropic strength of M-2 in order to reach a proper compromise between the required separation efficiency on the second column, and the desired peak compression (sensitivity of detection). It must be emphasized here, that the eluotropic strength, φ (fraction of organic of modifier), of M-1 must never exceed that of M-2 ($\varphi_{M-1} \leq \varphi_{M-2}$). During this part of the optimization one can, if required, tune selectivity by taking another type of hydrophobic column packing material or one from a different manufacturer or, in most cases firstly, by changing the mobile-phase constituents such as type of modifier, buffer and pH. The latter parameter can play a crucial role for the determination of acidic compounds in environmental water and soil samples.

In case of the on-line analysis of aqueous samples the attainable sensitivity is determined by LVI of standard solutions in HPLC-grade water. This is usually done by connecting C-1 to the UV detector which also provides the establishment of cleanup and transfer volumes. The maximum allowable sample injection volume, that is the volume that can be injected without excessive band

Figure 7 Performance of LVI in RPLC. Injection of standard bentazone (215 ng) in water containing 0.05% trifluoroacetic acid (TFA) (pH 2.4) on a 50 × 4.6 mm ID column packed with 3 µm Microspher C_{18} with a mobile phase of methanol–0.05% TFA in water, pH 2.4 (50 : 50, v/v) at a flow 1 mL min^{-1}. Injection volume: (a) 100 µL; (b) 2000 µL.

broadening of the analyte, largely depends on the C_{18} retention of analyte. For example, the small C_{18} retention of polar compounds such as CAAL and ETU (see Table 2) makes focusing of the analyte on the top of the column impossible, and because of migration of analyte during injection, band broadening rapidly starts to increase with increasing injection volume. In general, the start of peak deformation of the analyte upon injection on C-1 is selected as a criterion for the maximum allowable injection volume.

As demonstrated for bentazone in Figure 7, for analytes with sufficient retention ($k > 100$ in pure water as the mobile phase), RPLC allows LVI without additional band broadening. If sufficient sensitivity can not be obtained with a large volume loop injection below 8 mL, then an off-line concentration step such as SPE or liquid extraction will be necessary.

Finally, the total procedure is used to analyze real-life water samples and/or extracts. Insufficient selectivity can be improved by either re-adjustment of LC conditions or by changing the selectivity of the stationary and/or the mobile phase.

The important step to be considered in the development of on-line SPE/LC methods is the breakthrough volume of the analyte(s) on the small PC. During sample enrichment the mobile phase consists of pure aqueous sample and, therefore, breakthrough is mostly caused by insufficient retention. Breakthrough volumes can be accurately determined by measuring the UV signal of a water sample spiked with a pesticide and percolating through the PC connected to the detector.[12] A more practical way is to inject a small volume, e.g. 10 µL of concentrated standard of the pesticide in water onto the PC and determine the peak elution volume of the analyte using water as the mobile phase.

2.3 Systematic Method Development in Coupled Column Liquid Chromatography

The method development procedure discussed above is carried out in a rather straightforward way on the basis of trial-and-error experiments. The task of finding the adequate LC/LC conditions for separation between analytes and/or interference can be very difficult for the case of multiresidue analysis including compounds with a large and/or small difference in retention. For such cases, sophisticated method development procedures based on simulation and/or calculation were developed in order to avoid excessive experimental work.[13–15]

As a first step towards the development of dynamic MRMs for pesticides with LC/LC a simulation programme was developed.[13] It was based on a diffusion model; the main objective was an accurate prediction of retention times and peak volumes in order to formulate in a more effective way boundary conditions for development of MRMs using LC/LC.

Another step forward was to include the essential criteria involved in the optimization of step gradient elution in MRMs,[14] namely:

1. The first-eluting analyte must have a retention which is at least twice as large as that of the unretained compound (similar to SRM approach).
2. The total time of the chromatographic run should be kept relatively short (for sensitivity and sample throughput).
3. The resolution (Rs) between two adjacent peaks must be at least 1.2 to prevent problems due to UV wavelength switches and/or changes in the mobile-phase compositions.
4. The number of steps during gradient elution should be minimized to reduce baseline distortions and the complexity of the LC system.

Finally, a convenient and automated optimization procedure *OPTIME Version 3.1* has been developed.[15] *OPTIME Version 3.1* is based on the use of analytical equations for the prediction of chromatographic data (retention and peak volume) of analytes eluting under one- or two-step-gradient LC/LC conditions. The procedure is a constructed worksheet (Microsoft® Excel) and can be applied as a calculation and/or an optimization procedure.

In comparison to simulation, the developed calculation procedure enables a more rapid search for suitable

conditions for on-line cleanup and separation of analytes using coupled-column RPLC and is therefore highly productive and flexible.[15]

2.4 Liquid Chromatography/Ultraviolet Methods

The wide scope of both retention and detection of RPLC/UV enables fast separation and determination of many and various types of pesticides. Because of this favorable feature, RPLC/UV is frequently used in providing rather easy SRMs for the screening/monitoring of a limited number of target pesticides. In this context, RPLC/UV is attractive for use in the set-up of a screening method for recently developed polar pesticides.[16–20] The assay of the thermolabile, polar and relatively new insecticide imidacloprid in water and soil was rapidly performed with an RPLC/UV (270 nm) method using a 250 × 4.6 mm ID C_8 column with a mobile phase of methanol–water (20 : 80, v/v) at a flow rate of 1.5 mL min^{-1}. Extraction was performed with either SPE on 500 mg C_{18} columns (water) or with ACN (soil) and the analyte was determined in the uncleaned extracts to a level of 0.5 μg L^{-1} and 5 μg kg^{-1} in water and soil, respectively.[16] The simultaneous determination of six imidazolinone herbicides in natural waters was successfully carried out with off-line SPE (0.5 to 1 L of sample on 500 mg Carbograph-1) followed by RPLC/UV (240 nm); the analytes were separated on a 5 μm C_{18} column (250 × 4.6 mm) and a gradient elution with ACN, water and formic acid in water as mobile-phase constituents; the method includes the analysis of soils and confirmation of analytes with liquid chromatography/electrospray mass spectrometry (LC/ESMS).[17] A relatively new herbicide, thioazopyr and its mono-acid metabolite were assayed in groundwater with a simple method using SPE on graphitized carbon black (GCB) cartridges for sample treatment and RPLC/UV (220 nm) for instrumental analysis of the extracts obtained.[18]

Another relatively new class of herbicides are sulfonylurea herbicides characterized by low application rates and low toxicity to mammals. A number of RPLC/UV-based methods has been reported on the efficient determination of these herbicides in water and/or soil.[19,20] The combination of microwave-assisted solvent extraction (MASE) and RPLC/UV (226 nm) proved to be a convenient technique for the multiresidue analysis of sulfonylureas (5 tested) in soils down a level of at least 5 μg kg^{-1}.[19] After MASE (10 min), part (10 mL) of the organic solvent (dichloromethane–methanol, 90 : 10) was evaporated and the redissolved residues were analyzed with RPLC/UV in less than 15 min without additional cleanup. An important aspect was that samples with aged residues (60 days at 4 °C) were included in the method validation.[19]

A highly sensitive and rather selective high-performance liquid chromatography/ultraviolet (HPLC/UV) (230 nm) method for the determination of seven sulfonylureas in water was developed by Di Corcia et al.[20] Both selectivity and sensitivity were obtained by employing off-line SPE on 500 mg Carbograph 4 cartridges. This type of cartridge allows very large volume sampling (up to 4 L tested) without breakthrough of the sulfonylureas and stepwise elution of acid compounds. The latter feature avoids co-elution of humic acid interferences when using dichloromethane–methanol (80 : 20, v/v) acidified with acetic acid (10 mmol L^{-1}) as the solvent for desorption; confirmation of compounds was performed with electrospray mass spectrometry (ESMS) detection.[20] In the case of relatively large molecules, e.g. antibiotics, and/or very polar or ionic pesticides such as bipyridylium herbicides, RPLC provides an efficient separation. For example, efficient RPLC/UV methods have been developed for the residue analysis of warfarin in eggs[21] and spinosad and its metabolites in vegetables and fruits.[22]

Ion-pair/reversed-phase liquid chromatography (IP/RPLC) provides an efficient separation of ionic organic compounds. Despite the inherent LC pump wear of pistons and seals, IP/RPLC with UV detection is still the chosen technique for the determination of bipyridinium-type herbicides. Dedicated methods are available for the determination of diquat and/or paraquat in various type of matrices including mammal tissues[23] and biological fluids[24,25] and mammal tissue.[25] Because of their different UV spectra, detection is carried out at 257 and 308 nm for paraquat and diquat, respectively.

IP/RPLC with UV detection at 292 nm has been successfully applied for the simple, rapid and sensitive assay of 10 benzimidazole residues in milk[26] The method based on a pH-based liquid–liquid extraction (LLE) with ethyl acetate/buffer and the LC/UV analysis of uncleaned extracts enables determination of all compounds to a level of 5 μg L^{-1} with overall recoveries ranging between 70 and 100%.

Di Corcia et al.[27,28] developed a MRM for the monitoring of 89 pesticides in environmental waters. The group comprises base/neutral and acidic pesticides from various classes, e.g. carbamates, triazines, phenylureas, phenoxy acids and phenols. The method is based on the use of off-line SPE and HPLC/UV. In this method the role of the SPE on 300 mg Carbopack B cartridges is important. This GCB material allows sampling of water at a high-speed (120–130 mL min^{-1}) and provides selectivity by separating base/neutral from acidic analytes by means of a step-wise elution. Chromatographic analysis was performed on 250 × 4.5 mm ID columns packed with different 5 μm silica-bonded materials. For the base/neutral fraction (71 pesticides), the primary column contained a LC-C_{18}-DB (de-based) packing and the confirmation column contained a LC CN (cyano) packing. The acidic fraction (18 compounds) was separated on LC-C_{18}. The

separation of analytes was performed by optimized gradient elutions using ACN and buffered water as mobile constituents. UV detection was carried out at 220 nm and 230 nm for the determination of base/neutral and acidic pesticides, respectively. The limits of quantification (5 times the limit of detection LOD) were lower than 0.1 $\mu g\,L^{-1}$ for 84 pesticides and recoveries ranged between 80 and 105% with relative standard deviations (RSDs) below 10% for recoveries at low levels. The procedure was further modified by extending the analysis to very polar pesticides and metabolites by using 1 g GCB cartridges designed to perform re-extraction of the analytes in the back-flush mode.[29]

A general problem encountered in the RPLC/UV analysis of acidic pesticides in environmental samples is the presence of a broad hump in the chromatogram caused by the presence of co-extracted humic and fulvic acids. As will be discussed below, column-switching procedures employing sorbents with a different selectivity are available to improve significantly the chromatographic analysis. An effective off-line SPE procedure has been presented[30] employing cartridges packed with 200 mg of SDB-1 sorbent (styrene–diphenylbenzene). Beside the sufficient retention capacity of polar pesticides such as oxamyl and triazine metabolites deisopropylatrazine (DIA) and deethylatrazine (DEA) this material also retained the tested acidic pesticides (7 compounds) in their ionic form. This feature allowed sampling (500 mL) of water at pH 7 and eliminated largely the humic interferences making it possible to determine with RPLC/UV (220 nm) a group of 17 various pesticides in river water to a level of 0.1 $\mu g\,L^{-1}$.

Immuno-affinity-based extraction procedures offer high selectivity. This is clearly demonstrated by Pichon et al.[31,32] who developed immunosorbents for the selective SPE of phenylurea and triazine herbicides from environmental waters. The important advantage of the off-line immunosorbent is that it performs trapping of the majority of analytes of a chemical class (phenylurea, 9 out of 13; triazines, 6 out of 9), extending the scope of immunomethodology towards multiresidue analysis. The high selectivity is illustrated in Figure 8 showing the RPLC/UV (244 nm) analysis of phenylurea herbicides in extracts of surface water obtained after 200 mL of preconcentration on the immunosorbent cartridge.[31]

Figure 8 Off-line immuno-assay and RPLC/UV (244 nm) for the preconcentration of 200 mL of Seine River water (a) nonspiked and (b) spiked with 0.5 $\mu g\,L^{-1}$ of each of phenylurea herbicide on a cartridge containing silica bonded with anti-isoproturon antibodies. LC conditions: 250 × 4.6 mm ID 5 µm Supelcosil LC-18-DB column; ACN–water gradient elution consisting of 20 to 35% modifier from 0 to 52 min, 35 to 70% from 52 to 80 min, and 70 to 100% from 80 to 85 min. Peak assignment: (3) monuron, (5) chlortoluron, (7) isoproturon, (8) difenoxuron (9) buturon, (10) linuron, (11) chlorbromuron, (13) neburon. (Reprinted with permission from Pichon et al., *Anal. Chem.*, **67**, 2541–2460. Copyright © 1995, American Chemical Society.)

2.5 Solid-phase Extraction/Liquid Chromatography/Ultraviolet Methods

Fully automated SPE/LC methods using on-line trace enrichment, gradient elution and UV DAD were firstly directed to the multiresidue analyses of polar pesticides in various types of water.[6,33,34] Trace enrichment (100–150 mL of sample) was usually carried out with

an automated PC exchange system (Prospekt) using 10 × 2.0 mm ID disposable cartridges packed with 20 μm polymeric reversed-phase spherical packing (PLRP-S). Separation of analytes was accomplished on a 250 × 4.6 mm ID column packed with 5 μm C_{18} (DB) and gradient elution with ACN and 0.03 M phosphate buffer (pH 3) as mobile phase constituents. The effectiveness of DAD in providing very well matched UV spectra for confirmation of pesticides and or metabolites in European rivers, traced at levels between 0.05 and 1.4 μg L^{-1} has been clearly demonstrated.[6,7,33] Direct automated evaluation of data integrated in the fully automated LC-system resulted in an early warning system called SAMOS which has been successful in the determination of 27 organic micropollutants at concentrations of 1 μg L^{-1} in surface waters.[6,7] It is interesting to note here that for compounds amenable to GC the same automated sample pretreatment procedure was used, providing a solid-phase extraction/gas chromatography (SPE/GC) based SAMOS.[35]

The SPE/LC SAMOS approach was further optimized by a more efficient separation of analytes involving the use of a 150 × 4.6 mm ID column packed with 3.5 μm Zorbax SB-C_{18}, a column temperature at 43 °C;[36] buffering (pH of 7) of the mobile phase with ammonium acetate significantly improved the peak shape of some triazines.[36] The improved conditions allowed the automated SPE/LC/DAD analysis of triazine and phenylurea herbicides in raw and drinking water with LODs ranging between 0.002 and 0.012 μg L^{-1}. Confirmation with UV DAD was accomplished, even at levels near to the LODs. Requiring an analytical run time of 65 min for adequate separation of analytes and the analyses of standards, the system is able to process about 10 samples per day.

Up to about 110 compounds representing many classes of polar compounds were determined on-line with SPE/LC/DAD.[37] This study emphasized that beside important parameters such as sample pH, column temperature and elution conditions, the type of LC column was found to be the most important parameter. From the six columns tested the 150 × 4.6 mm ID column packed with 3.5 μm Zorbax SB-C_{18} provided the highest selectivity/sensitivity. The very good performance of DAD confirmation of phenolic compounds in case of base-line distortion caused by humic acid interferences is shown is Figure 9. Decrease of the base-line distortion in the first part of chromatogram was achieved by applying on-line dual PCs (both 10 × 2 mm ID, packed with 15–25 μm PLRP-S). With this approach, the highly polar compounds which showed breakthrough on the first PC were trapped on the second one while most of the humic substances are retained on the first one.

In comparison to PCs, hydrophobic membrane extraction disks (SPEDs) appeared to be a good alternative with respect to sorption, capacity, back-pressure and stability

Figure 9 SPE/LC/DAD/UV (215 nm) chromatogram of a surface water sample spiked with dichlorobenzoic acids and bentazone at the 1 μg L^{-1} level. Peaks: (1) 2,6-dichlorobenzoic acid, (2) 2,3-dichlorobenzoic acid, (3) 2,5-dichlorobenzoic acid, (4) 2,4-dichlorobenzoic acid, (5) bentazone, (6) 3,4-dichlorobenzoic acid. Analytical conditions: 10 × 2 mm ID 15–25 μm PLRP-S SPE cartridge; sampling of 50 mL of water sample acidified with hydrochloric acid to pH 2; 250 × 4.6 mm ID 5 μm Zorbax-RX column; LC gradient of ACN–10 mM phosphate buffer of pH 2 from 10% to 80% modifier in 30 min; column oven temperature, 40 °C. Insets: UV absorbance spectra of analytes. (Reproduced with permission from Hogenboom et al., *Analyst*, **122**, 1371–1377. Copyright © 1997, The Royal Society of Chemistry.)

after repeated use.[38–40] A simple leak-tight membrane disk holder offering flexibility in choosing type, size and number of disks was developed to perform on-line operation.[38,39] Solid-phase extraction disk/liquid chromatography/ultraviolet/diode array detection (SPED/LC/UV/DAD) methods allowed the rapid trace level determination of three basic pesticides (carbendazim, chloridazon, simazine)[39] and nine neutral pesticides (carbamates, phenylureas)[40] in river and drinking water, respectively.

The simultaneous on-line determination of the diquat, paraquat and difenzoquat in water at levels of 0.1 μg L^{-1} was carried out with SPE/LC/UV.[41,42] Sampling and separation of analytes was performed on Hypercarb-GCB[41] or bare silica material[42] employing sampling volumes of 50 (on GCB) or 200 mL (on silica), respectively.

A distinct advantage of on-line SPE systems is to improve selectivity by using SPE columns packed with an analyte(s) trapping sorbents of a different separation mechanism. One must take care that the desorption kinetics are fast enough to avoid a large loss of efficiency. For example, this drawback occurs in combining carbon materials, which have the best enrichment properties, with a C_{18} analytical column.[43] Methods based on use of selective SPE sorbents have been developed for the fully automated analysis of chlorophenoxy acid herbicides in water by using either a PRP-1 and anion-exchange PC in series[8] or a PC in combination with pH step-gradient from 2.8 (sampling) to 8.8 (desorption) followed by ion-pair LC separation at pH 8.8.[44] Both methods allowed the determination of the acidic pesticides in tap water at levels between 15 and 30 ng L^{-1}. For the on-line SPE/LC determination of a group of phenolic and neutral pesticides, interference of humic acid was significantly decreased by using a modified polymeric resin (*o*-carboxybenzoyl moiety) in combination with addition of sodium sulfite salt to the water sample.[45]

A new development in improving selectivity of the on-line SPE/LC techniques is the use of pressure resistant immunosorbents for trace enrichment. Especially, the availability of material providing sufficient cross-reactivity to pesticides of a same chemical class makes this technique more attractive for use in multiresidue analysis. Based on this approach methods have been developed for the simultaneous on-line trace analysis of phenylurea herbicides in environmental water using a silica-based immuno-[46] or mixed-immuno silica-based sorbent.[47]

Recently, Kok and Hiemstra[48] presented an overview of their developed HPLC methods[1,48–51] used in daily practice for the efficient screening of polar and/or thermolabile pesticides in fruits and vegetables. The five SPE/LC based methods are schematically presented in Figure 10 and cover a total of about 100 pesticides including the classes: benzoylphenylureas,[49] benzimidazoles,[50] conazoles,[48] carbamates,[51] and phenylureas.[1,48] Study and validation demonstrated[48] that the efficient and miniaturized extraction (see Figure 10) used for the GC MRMs[1] was also applicable for extraction of the polar pesticides. Each SPE/LC procedure was fully automated by means of a commercially available SPE apparatus (ASPEC). Concerning carbamates and phenylureas more information about method performance will be given in section 3.2. The separation of benzimidazoles (carbendazim/thiabendazole) and conazoles (imazalil/prochloraz) were performed on a 150 × 8 mm ID column packed with Shodex Rspak DE-613 polymer material and a 250 × 4.6 mm ID column packed with Inertsil ODS-3, respectively. The mobile phase consisted of 70% ACN (conazoles) or methanol (benzimidazoles) in phosphate buffer pH 7. The SPE cleanup on the diol cartridges appeared to be very effective. It allowed UV detection at 210 nm of imazalil and prochloraz at a level of 0.1 mg kg^{-1} without the occurrence of interfering peaks from the various types of blank commodies (foodstuffs) investigated. Also for carbendazim and thiabendazole this cleanup provided high selectivity.[50]

Benzoylphenylureas were separated on a 150 × 3 mm ID column packed with 4 µm Superspher 60 RP-8 and using an ACN–water gradient of 15 min at flow of 0.5 mL min^{-1}. The good performance of the LC method is shown in Figure 11 for the analysis of an extract of a green pepper spiked with analytes at a level of 0.1 mg kg^{-1}. Additional confirmation was obtained with DAD and unambiguous identification was done with GC/MS using either electron impact (EI) and/or chemical ionization (CI) mode. The limit of determination of the method was 20 µg kg^{-1} for each compound. All LC methods allowed the determination of these pesticides far below the MRLs.

2.6 Coupled Column/Ultraviolet Methods

An overview of on-line LC/LC/UV methods[9–11,52–57] for the trace analysis of various pesticides and related compounds in water samples is made in Table 3. The simplicity and effectiveness of the LC/LC/UV analyzer (see Figure 5) provides selective methods with a high sample throughput (run times of about 10 min). As discussed above and illustrated by the data given in Tables 2 and 3 the LVI in case of very polar analytes is limited. Hence, for compounds like CAAL and ETU, LVI is limited to 0.2–0.5 mL yielding LODs in the range of 1 µg L^{-1}. By the use of relatively simple manual concentration steps the LODs can be lowered to the EC drinking-water limit of 0.1 µg L^{-1}.[52–54] For compounds with sufficient C_{18} retention and UV detection (see Table 2) LODs of 0.1 µg L^{-1} can be obtained employing sample injections below 8 mL (see data of Tables 2 and 3). Figure 12 clearly demonstrates the performance of LC/LC/UV analysis: the trace analysis of isoproturon in surface water in less than 8 min. It also shows the significant improvement in selectivity of LC/LC in comparison to the use of two coupled C_{18} columns without column switching, a phenomena also encountered in ion chromatography.[58]

A rather unexpected matrix-dependent retention time was reported in the simultaneous determination of bromacil and in diuron employing LVI LC/LC/UV.[55] Investigating LC grade, drinking and surface water differences in retention times of about 1 min were observed indicating that one must consider this effect in LC/LC method development. Nevertheless, the LC/LC method is distinctly more efficient in comparison to the method previously in use, which employed a laborious sample pretreatment step.[59]

Figure 10 Scheme of MRMs as applied for the determination of polar pesticides in fruits and vegetables and according to refs. 48–51.

Figure 11 RPLC/UV (260 nm) of an extract of a green pepper sample spiked with benzoylphenylurea pesticides at a level of 0.1 mg kg^{-1}. Sample pretreatment is given in Figure 10. LC conditions: 150 × 3 mm ID 4 µm Superspher 60 RP-8 column with an ACN–water gradient elution from 25 to 50% in 15 min. Peaks: 1. diflubenzuron; 2. triflumuron; 3. triflubenzuron; 4. hexaflumuron; 5. lufenuron; 6. flufenoxuron; 7. chlorfuazuron.

The SRMs shown in Table 3 make use of small transfer volumes, typically 0.2–0.9 mL, in order to enhance selectivity. Although expected, the MRMs requiring larger transfer volumes[57] did not offer sufficient selectivity. This emphasizes that in LC/LC the performance of an efficient cleanup on C-1, which means the removal of S1, is a predominant selectivity parameter for this type of analysis. The performance of on-line multiresidue analysis of triazines in surface water at a level of 0.4 µg L^{-1} is given Figure 13.

The examples discussed above clearly demonstrate the main advantage of on-line LC/LC/UV: the fast screening of a wide variety of compounds in environmental water samples. For analytes with sufficient UV absorption/selectivity (ε and λ values of more than 15 000 L mol^{-1} cm^{-1} and 220 nm, respectively) and C_{18} retention ($k > 50$, in pure water) LODs in the range of 0.1 µg L^{-1} are feasible. However, owing to its maximum

Table 3 Conditions and performance of LC/LC/UV methods for the on-line analysis of pesticides in water

Analyte	C-1[a]	C-2[a]	M-1	M-2	Injection volume (mL)	Cleanup volume (mL)	Transfer volume (mL)	UV (nm)	LOD ($\mu g\,L^{-1}$)	Time of analysis (min)	Ref.
Bentazone	A	B	MeOH–buffer,[b] pH 2.3 (50:50)	MeOH–buffer,[b] pH 2.7 (50:50)	2.0	4.65	0.45	220	0.1	8	9

Bromacil, diuron	D	B	MeOH–water (30:70)	MeOH–water (65:35)	2.0	5.00	0.90	277	0.1	10	55
Simazine, atrazine, terbuthylazine, terbutryn	D	B	ACN–water (40:60)	ACN–water (70:30)	2.0	2.90	0.70	223	0.1	7	56
Atrazine, DIA, hydroxy-atrazine and DEA	D	E	ACN–water (20:80)	ACN–water (35:65)	2.0	2.60	4.20	220	0.3	12	57

[a] Type of columns: A, 50 × 4.6 mm ID packed with 3 µm Microspher C_{18}; B, 100 × 4.6 mm ID packed with 3 µm Microspher C_{18}; C, 150 × 4.6 mm ID packed with 5 µm Hypersil ODS; D, 30 × 4.6 mm ID packed with 5 µm Spherisorb ODS-2; E, 125 × 4.6 mm ID packed with 5 µm Spherisorb ODS-2.
[b] 0.1% phosphoric acid in water.
[c] Containing 0.2% of ammonia.

sample injection volume of about 8 mL the on-line LC/LC/UV approach is not viable for pesticides with sufficient C_{18} retention but having ε values below about 14 000, e.g. chlorophenoxy acid herbicides (see Table 2).

2.7 Coupled Column/Ultraviolet Methods Employing Off-line Solid-phase Extraction

In order to employ the favorable LC/LC/UV features (efficient removal of S1) an off-line preconcentration step will be necessary for the trace analysis of compounds with insufficient UV sensitivity (see above).

Besides enhancement of sensitivity, off-line extraction procedures can offer distinct advantages above on-line procedures in this field of analysis. For example, organic extracts (concentrated) obtained by off-line procedures, e.g. LLE or SPE may be stored over a longer period of time so that they can be analyzed in batches. This is more efficient in case of monitoring studies involving small series of samples with a low frequency of sample collection over a long period of time.

In studies involving the determination of pesticides of different chemical families, operational MRMs as applied in monitoring programs are often applied in combination with GC-based MRMs. It is then often more convenient to use a unified extraction/concentration procedure with an organic solvent or (semi) automated SPE, so that the same extract can be used for all MRMs to be applied on a sample.

A comparison between LVI on-line LC/LC/UV and off-line SPE combined with LC/LC/UV for the trace analyses of triazines and some metabolites in water samples showed similar results: on-line LC/LC/UV favors speed of analysis while a simple preceding off-line SPE step provides LODs in the range of 0.02–0.05 $\mu g\,L^{-1}$.[57] Another comparative study included the use of hydrophobic on-line SPE/LC (PC/LC).[60] It appeared that in comparison to LVI LC/LC/UV and off-line SPE combined with LC/LC/UV, PC/LC favors sensitivity and speed of analysis at low levels ($<0.1\,\mu g\,L^{-1}$) but selectivity is considerably less.

Figure 12 LC/LC/UV (244 nm) of surface water sample spiked with isoproturon at a level of 0.5 μg L^{-1}. LC/LC conditions, see Table 3.[9] A, chromatogram obtained with column switching; B, chromatogram using the two columns in series without column switching.

Off-line SPE and LC/LC/UV were successfully applied in an interlaboratory study involving the determination of phenylurea herbicides spiked at levels of about 0.1 μg L^{-1} to drinking water, groundwater and surface water. The SPE procedure involved the sampling of 250 mL of water on a 500 mg C_{18} SPE cartridge preconditioned before use with 3 mL of methanol, 3 mL of acetone, 3 mL of methanol and 6 mL of LC-grade water. After sample loading, the cartridges were dried by passing air for 30 min and the analytes were eluted with 2 mL of acetone. An aliquot of the acetone corresponding to 125 mL of sample was transferred in a tube and evaporated to dryness with a gentle stream of nitrogen. The residue was redissolved by adding first 0.20 mL of ACN followed by 1.8 mL of LC-grade water. The LC/LC/UV analysis displayed in

Figure 13 LC/LC/UV (233 nm) of a surface water sample spiked with triazine herbicides at a level of 0.4 μg L^{-1}. LC conditions, see Table 3.[56] Peaks: (1) simazine, (2) atrazine, (3) terbuthylazine, (4) terbutryn.

Figure 14 Off-line SPE and LC/LC/UV (244 nm) of an SPE extract of a surface water containing (1) monuron (0.18 μg L^{-1}), (2) monolinuron (0.70 μg L^{-1}) and (3) diuron (0.20 μg L^{-1}). LC conditions: C-1, 3 μm Microspher C_{18} (50 × 4.6 mm ID); C-2, 3 μm Microspher C_{18} (100 × 4.6 mm ID); M-1 and M-2, methanol–water (55 : 45, v/v) both at 1 mL min^{-1}; injection 150 μL of SPE extract (procedure, see Text); cleanup volume, 1.3 mL; transfer volume, 3.4 mL.

Figure 14 of a surface water sample containing monuron, monolinuron and diuron at a level of 0.18, 0.70 and 0.20 μg L^{-1}, respectively nicely demonstrates the good performance of this approach on both selectivity and sensitivity.

A new development in the determination of acidic compounds in environmental samples is the beneficial

Figure 15 Schematic presentation of retention mechanism of the 5 µm GFF-II ISRP material. Outer layer, glycine (polar); Inner layer, glycine–phenylalanine (nonpolar).

use of analytical columns packed with restricted access material (RAM). As schematically presented in Figure 15 for internal surface reversed-phase (ISRP) material, efficient separation is obtained between small molecular analytes and large molecular substances. Originally, RAM columns were developed for the on-line processing of body fluids such as serum and blood providing retention for analytes but eluting large molecules, e.g. proteins, in the void column volume.[61–63]

The RPLC/UV analysis of acidic pesticides (small molecules) in environmental samples is usually severely hampered by co-extracted humic substances (large molecules) which show up as a broad hump in the chromatogram. Indeed, improved chromatographic performance was obtained for determination of a group of chlorophenoxy acid herbicides in environmental waters by SPE/LC/UV (220 nm) employing a PC packed with ISRP 5 µm GFF-II, RAM.[64] Unfortunately, the ISRP PCs of different batches showed poor reproducibility in the required retention of the analytes, hence providing insufficient selectivity.

Improved results were obtained when employing RAM columns in the LC/LC mode, that is, using analytical RAM columns. In a recent comprehensive study[65] the applicability of several commercially available analytical RAM columns in LC/LC/UV for the trace analysis of acidic herbicides in water samples was investigated. Different LC configurations were studied including the single RAM column mode and column switching LC/LC employing one RAM column in combination with an analytical C_{18} column or two RAM columns. Involving a group of acidic herbicides representing different chemical families, both the SRM and MRM approach were tested by analyzing SPE C_{18} extracts of reference water samples spiked with the analyte(s) at the 0.5–1.0 µg L^{-1} level and containing dissolved organic carbon (DOC) between 3 and 12 mg L^{-1}. Information on the type of RAM of columns studied and adequate coupled column conditions is given in Table 4.

As regards SRM the use of one analytical RAM or two different types of RAM columns sufficiently improved the resolution between the analyte and the interference of humic acids to perform trace analysis in the SPE extracts with a preceding cleanup. Figure 16 demonstrates the effectiveness of the LC/LC approach involving an ISRP column as the C-1 for the single residue analysis of the polar metsulfuron-methyl herbicide at a level of 1 µg L^{-1}.

Table 4 Overview of LC/LC methods using analytical RAM columns for the trace analysis of acidic herbicides in uncleaned SPE extracts[a] of DOC containing (6–12 mg L^{-1}) water samples

Method	Herbicides	C-1[b] and M-1[c]	C-2[b] and M-1[c]	Cleanup/transfer volume (mL)
SRM	MCPP	C_{18} (50 × 4.6 mm ID); 60%	SPS (150 × 4.6 mm ID); 60%	3.6/1.0
		SPS (50 × 4.6 mm ID); 60%	Hisep (50 × 4.6 mm ID); 60%	4.0/1.0
		Hisep (50 × 4.6 mm ID); 60%	C_{18} (100 × 4.6 mm ID); 60%	3.5/1.0

MRM	Bentazone, bromoxynil	C_{18} (50 × 4.6 mm ID); 35%	SPS (150 × 4.6 mm ID); 40%	2.9/0.9
MRM	Bentazone, bromoxynil, metsulfuronmethyl, MCPA, MCPP	ISRP (50 × 4.6 mm ID); 40%	C_{18} (50 × 4.6 mm ID); 60%	2.3/2.9
		ISRP (50 × 4.6 mm ID); 40%	SPS (50 × 4.6 mm ID); 55%	2.2/3.6
		C_{18} (50 × 4.6 mm ID); 52.5%	SPS (50 × 4.6 mm ID); 52.5%	1.9/5.9

[a] Procedure. Passing of 250 mL of water sample (brought to pH 2.2 with HCl) through a 500 mg C_{18} cartridge. Desorption with 2 mL of acetone. After evaporation acetone, residue is redissolved in 0.4 mL methanol and 1.6 mL of 0.1 TFA in water.
[b] Packing materials: C_{18}, 3 µm Microspher C_{18} (Chrompack); SPS, 5 µm SPS-5PM-S5-100-ODS (Regis); ISRP, 5 µm Pinkerton ISRP GFF-II-S5-80 (Regis); Hisep, 5 µm Hisep (Supelco).
[c] Modifier content in mobile phase consisting of methanol–0.03 M phosphate, pH 2.4 (v/v).

Figure 16 LC/LC/UV (220 nm) using the ISRP/C_{18} column combination for the analysis of a SPE extract of a water sample containing 12 mg L^{-1} DOC and spiked with metsulfuron-methyl at a level of 1 µg L^{-1}. Injection volume, 300 µL. SPE and LC/LC conditions, see Table 4.

Both ISRP and Hisep RAM columns provide a very efficient preseparation between acidic analytes and humic interferences. However, these columns showed, in comparison to C_{18}, a different separation mechanism which resulted in a reversed elution order and a significant increase of band broadening for some of the analytes. This feature can be disadvantageous in the MRM of pesticides of various classes. The good performance of LC/LC/UV involving the C_{18}/SPS analytical column combination is demonstrated in Figure 17 showing the simultaneous trace analysis of a group of acidic pesticides from different classes in water containing a DOC content of 6 mg L^{-1} and spiked with the analytes at the 0.5–1.0 µg L^{-1} level.

In comparison to water, soil will contain more interferences. Hence, cleanup will be even more important in the analysis of soil extracts, therefore LC/LC is an attractive technique to perform efficient on-line cleanup. In a monitoring program aimed at the occurrence of the more persistent pesticides, two LC/LC/UV based screening methods were developed for the analysis of the pesticides pencycuron and fenpropimorf in soil.[9] A simple sample extraction/concentration procedure was applied employing an overnight standing of soil in ACN followed by a filtration and a concentration step. The gain in selectivity provided by LC/LC is demonstrated in Figure 18 which shows the RPLC/UV (215 nm) analysis of soil spiked with 50 µg kg^{-1} of fenpropimorf.

As has been demonstrated recently, the use of an analytical RAM column in LC/LC/UV is also favorable

Figure 17 LC/LC/UV (220 nm) using the C_{18}/SPS column combination for the analysis of a SPE extract of a water sample containing 6 mg L^{-1} DOC and spiked with acidic pesticides at the 0.5–1.0 µg L^{-1} level. Injection volume, 300 µL. SPE and LC/LC conditions, see Table 4. Analytes (and levels): (1) metsulfuron-methyl (0.5 µg L^{-1}); (2) bromoxynil (0.5 µg L^{-1}); (3) bentazone (0.5 µg L^{-1}); (4) MCPA (1 µg L^{-1}); (5) MCPP (1 µg L^{-1}).

Figure 18 LC/LC/UV (215 nm) analysis of 100 µL of extract (corresponds to 50 mg of soil) of a soil sample spiked with fenpropimorf at a level of 50 µg kg^{-1}. LC/LC conditions: C-1, 5 µm Hypersil SAS (60 × 4.6 mm ID); C-2, 5 µm Hypersil ODS (150 × 4.6 mm ID); M-1, ACN–0.5% ammonia in water (50 : 50; v/v); M-2, ACN–0.5% ammonia in water (90 : 10; v/v); flow rates, 1 mL min^{-1}; cleanup volume, 5.9 mL; transfer volume, 0.45 mL. A, chromatogram obtained with column switching; B, chromatogram using the two columns in series without column switching and using M-2 as the mobile phase.

for the analysis of acidic compounds in soils.[66] For the screening of MCPP in soils a LC/LC/UV method has been developed using a 50 × 4.6 mm ID RAM column packed with 5 µm ISRP (Pinkerton) as C-1. It appeared that in comparison to an analytical C_{18} column the ISRP column substantially improved the separation between acidic analyte and co-extracted humic substances. Under the selected LC/LC conditions uncleaned soil extracts obtained after a rapid extraction/concentration procedure were directly processed with LC/LC/UV (220 nm) allowing the determination of MCPP in soils to a level of 0.02 mg kg^{-1}.[66]

3 REVERSED-PHASE LIQUID CHROMATOGRAPHY WITH FLUORESCENCE DETECTION

3.1 Liquid Chromatography/Fluorescence Detection Methods

FD measuring the emitted light after the absorption of light by a compound both at a specific wavelength is very selective and sensitive. Compounds that normally undergo fluorescence can have a 100–1000-fold increase in sensitivity over UV detection, making it attractive to be used in pesticide residue analyses. Unfortunately, very few pesticides have a favorable fluorophore. A good example is the antiparasitic agent ivermectin for which a selective and sensitive method has been developed for its determination in animal tissues at the low parts per billion level.[67]

Pre- or postcolumn derivatization techniques have substantially extended the use of FD in this field of analysis.[68,69] The most widely adopted technique is the postcolumn reactor for the detection of *N*-methylcarbamates. After the RPLC separation a two-stage postcolumn reaction system provides hydrolyses of analytes to methylamine and reaction of this product with *o*-phthalaldehyde (OPA) for the formation of a highly fluorescent derivative. This approach has been introduced by Moye et al.[70] and further modified and optimized by Krause[71] providing robust, selective and sensitive methods for the multiresidue determination of *N*-methylcarbamates in crop samples.[72–74] The SPE cleanup of the organic extracts on a cartridge packed with bonded aminopropyl-silica and carried out in the normal-phase mode appeared to be effective and rapid.[48,51] The robustness of the OPA postcolumn reaction detection is also emphasized by forming the basis of the United States Environmental Protection Agency (USEPA) Method 531.1[75] for the determination of *N*-methylcarbamate pesticides in environmental water samples.

Optimization of hydrolysis by means of a solid-phase reactor consisting of a column packed with anion-exchange material distinctly simplified the post-column derivatization technique and extended the analysis to 22 carbamate pesticides and 10 metabolites in crops with LODs in the range of 1–10 µg kg^{-1}.[76] The same approach including off-line SPE of 50 mL of sample on cartridges packed with 500 mg of low-carbon C_{18}-bonded silica (C_{18}/OH) for trace enrichment provided a method for determination of 20 carbamates and 12 metabolites in surface water at the low ng L^{-1} level;[77] a 250 × 4 mm ID column packed with 4 µm Superspher 60 RP-8 was used for the separation of carbamates and metabolites using ACN–water gradient of 30 min at flow of 1 mL min^{-1}.

Another approach to hydrolysis of carbamates and *N*-containing pesticides such as phenylureas prior to derivatization with OPA was introduced by Miles and Moye who employed a photolytic reactor consisting of a UV lamp inserted in the center of a woven coil of Teflon™ tubing.[78] The postcolumn on-line photochemical reactor in combination with fluorescence, electrochemical or conductivity detection provided MRMs for the assay of over 100 pesticides in the groundwater samples.[79]

PC derivatization using 1-methylimidazole and TFA was successfully applied for the LC/FD determination of the large molecular compound abamectin in forest matrices including water, soils and foliage.[80] Sample pretreatment consisted of an extraction with dichloromethane and cleanup with Florisil column chromatography. Limits of quantification were 0.2 µg kg^{-1} and 0.01 µg L^{-1} for solid and water samples respectively.

3.2 Solid-phase Extraction/Liquid Chromatography/Fluorescence Detection Methods

Hiemstra and Kok[81] transformed the method involving off-line SPE[76] into a completely automated method for the determination of carbamates in water. The study included the testing of two different, commercially available, automated trace enrichment devices (Prospekt and OSP-2). Both trace enrichment systems showed a good method performance and with small sampling volumes of 3 mL (OSP-2 system) or 5 mL (Prospekt system) detection limits (DLs) of the carbamates and their metabolites for surface water were between 30 and 50 ng L^{-1}; the sample throughput was about 30 samples per 24 h.

The same degree of automation was obtained for the processing of crop extracts by means of an automated SPE cleanup apparatus.[51] This system (ASPEC), performs cleanup on a SPE amino-bonded silica column and, after a solvent switch, the injection of part of the extract into the LC carbamate analysis system (see Figure 10). The good results on recovery and repeatability from 13 carbamates and 12 metabolites on 12 different types of

food products and the registration of control samples in Shewhart charts during several years of routine analysis have clearly demonstrated the good performance of this approach.[48,51]

In the analysis of *N*-methyl carbamates employing LC, hydrolysis, OPA derivatization and FD, on-line and off-line cleanup of vegetable extracts has been carried out by using activated carbon membranes.[82] The highly retentive property of the SPED material allowed direct injection of 20 µL of toluene-modified ACN extract and provided an effective retention of sample interferences. The method tested on green peppers spiked at a level of 0.25 mg kg^{-1} with 10 carbamates provided recoveries at levels between 56–93% and 87–99% for the on-line and off-line SPED cleanup, respectively.

The combination of postcolumn photolysis by means of UV irradiation at 254 nm, derivatization with OPA and FD[79,80] has been successfully applied for the monitoring of phenylurea herbicides in foodstuffs.[1,48] The instrumental analysis displayed in Figure 19 of an uncleaned extract of a carrot sample fortified with 0.1 mg kg^{-1} of phenylurea herbicides shows the good performance and the high selectivity/sensitivity of this approach; if necessary, an automated SPE sample cleanup can be included in the method (see Figure 10).

Figure 19 RPLC with FD (ex: 340 nm, em: 455 nm) with reaction detection involving post-column photolysis and derivatization with OPA of an uncleaned extract of a carrot sample spiked with phenylurea herbicides at a level of 0.1 mg kg^{-1}. Sample pretreatment is given in Figure 10. LC conditions: 250 × 4.6 mm ID 4 µm Superspher 60 RP-8 column with an ACN–water linear gradient elution from 35 to 60% of modifier in 30 min at flow of 1 mL min^{-1}; photolysis, knitted reaction coil (250 × 5 mm) and irradiation with UV at 254 nm. Peaks: 1. fenuron; 2. metoxuron; 3. monuron; 4. chlorotoluron; 5. flurometruron; 6. isoproturon; 7. difenoxuron; 8. metobromuron; 9. buturon; 10. linuron; 11. chlorbromuron; 12. neburon.

3.3 Coupled Column/Fluorescence Detection Methods

The LC/LC/FD technique has been successfully applied for the efficient determination of phosphinic acid herbicides glufosinate and glyphosate and glyphosate's metabolite amino methyl phosphonic acid (AMPA).[83–85] These herbicides are widely used in agriculture as nonselective contact herbicides. Because of their high polarity, amphoteric properties and poor detectability, methodology to determine these compounds at trace levels requires a large effort in sample preparation steps such as extraction, concentration, derivatization and cleanup. A study on the determination of glufosinate in environmental water samples[83] demonstrated that the combination of PC derivatization with 9-fluorenylmethylchloroformate (FMOC-Cl) and LC/LC/FD considerably improves the sample throughput. The method uses a C_{18} column coupled to an ion-exchange amino column with a mobile phase of ACN–0.05 M phosphate buffer, pH 5.5 (35 : 65, v/v) for both columns.

It must be emphasized that the cleanup performance here is obtained in a reversed way. Instead of removing an excess of early eluting interferences (S1, see also Figures 3 and 5) one advantageously makes use of the amphoteric property of FMOC–glyphosate. In the LC/LC approach the mobile phase ionizes the analyte which will result in little C_{18} retention on C-1 and an adequate retention on C-2. The efficient cleanup is obtained by transferring an almost unretained small-analyte-containing fraction from C-1 to C-2. All interferences with more C_{18} retention, e.g. the excess of FMOC-OH, are retained on C-1 and sent to waste by the rinsing mobile phase during the separation of the analyte on C-2.

It was established that LVI could be achieved by reducing the percentage of modifier (40% ACN is required for adequate derivatization with FMOC) with an aqueous borate buffer solution before injection. For example, a four-fold dilution step allowed the injection of 2.0 mL of sample without significant band broadening of the polar FMOC–glufosinate during injection on the C_{18} column (C-1). However, in the mobile phase (M-1) the C_{18} retention of an ionic FMOC-phosohic acid is very little and the analyte will elute then almost as an unretained compound. Hence, shortly after LVI the analyte will be transfered to the amino column (C-2) in a relatively small volume (approx. 250 µL) In this way an efficient preseparation between the large excess of the FMOC reagent and the FMOC analyte is realized.

The usefulness of this approach was also investigated for the determination of glyphosate and its main metabolite AMPA in environmental water samples.[84] It appeared that for glyphosate an eight-fold dilution step was necessary to avoid excessive band broadening of

Figure 20 LC/LC/FD (ex: 263 nm, em: 317 nm) of a 2 mL solution obtained after derivatization with FMOC and 8-fold dilution with a borate buffer[84] of a surface water sample spiked with the analytes at a level of 4 μg L^{-1}. LC/LC conditions: C-1, 5 μm C_{18} (30 × 4.6 mm ID); C-2, 5 μm NH2 (250 × 4.6 mm ID); M-1 and M-2, ACN–0.05 M phosphate buffer, pH 5.5 (35 : 65, v/v) both at a flow of 1 mL min^{-1}; cleanup volume, 2.21 mL (injection volume included); transfer volume, 0.53 mL. Peaks: 1. AMPA; 2. glufosinate; 3. glyphosate. (Reprinted from Sancho et al., 'Rapid Determination of Glufosinate, Glyphosate and AMPA in Environmental Water Samples Using Precolumn Fluorogenic Labeling and Coupled-column Liquid Chromatography,' *J. Chromatogr. A.*, **737**, 75–83. Copyright © 1996 with permission from Elsevier Science.)

glyphosate–FMOC during LVI. Glufosinate, glyphosate and AMPA could indeed be assayed simultaneously in aqueous samples at a level of 1 μg L^{-1} with a high sample throughput. An example of this approach is given in Figure 20, showing the LC/LC/FD analysis of surface water sample spiked with three analytes at the level of 4 μg L^{-1}.

SRMs focused on the analysis of one analyte applying very accurately adjusted volumes for dilution, cleanup and transfer allowed the determination down to the 0.1 μg L^{-1} level.

Employing SRMs, glufosinate, glyphosate and AMPA were successfully recovered from water samples at 0.5–10 μg L^{-1} level fortification levels, with a sample throughput of at least 40 samples per day.[84]

The same approach has been applied for the determination of glyphosate and AMPA in soil samples.[85] After extraction in alkaline media an aliquot of the extract is neutralized and processed with the procedures mentioned above. Depending on the type of soil, whether it had high or low clay content and organic matter, limits of determination are 100 and 10 μg kg^{-1}, respectively for both analytes.

4 REVERSED-PHASE LIQUID CHROMATOGRAPHY WITH MASS SPECTROMETRIC DETECTION

4.1 General Aspects

The possibility of performing determination and unambiguous identification of polar pesticides simultaneously makes LC with MS detection an attractive and fast growing technique in the field of PRA. In comparison to the usually applied universal UV or photodiode array detectors, confirmation analysis with MS detection is usually not encountered with problems like (almost) identical UV spectra of compounds of a same class (e.g. phenylureas) or compounds lacking a chromophore (e.g. phosphonic acids). This results in liquid chromatography/mass spectrometry (LC/MS) having a high potential for analyzing a broad spectrum of pesticides and, hence, potentially a high productivity in multiresidue analyses.

The principles of the various LC/MS interfaces and the various types of interfaces as applied for the determination of polar pesticides have been described.[86] Until the mid-1990s most applications involved thermospray (TSP) or particle beam (PB) interfaces.[86] The advantage of obtaining EI spectra when using the PB interface makes liquid chromatography/particle beam mass spectrometry (LC/PBMS) very powerful in the detection and determination of polar pesticides. Several LC/PBMS based MRMs have been developed for the trace analysis of triazines, phenylureas and/or carbamates in water samples employing off-line[87,88] or on-line[89–92] solid extraction procedures. The possibility to obtain positive and/or negative CI spectra and to compare data to GC/MS data bases is an important feature of this technique, but evidently concerns only GC-amenable pesticides such as triazines and organophosphorus compounds.[92]

In comparison to the PB interface, liquid chromatography/thermospray mass spectrometry (LC/TSPMS) is more compatible with conventional HPLC-system mobile phases, including solvent additives, and offers in most cases higher sensitivity. Based on studies[93–95] investigating optimal TSP ionization conditions for pesticides, several LC/TSPMS MRMs including the determination of numerous pesticides of different classes, e.g. phenylureas, carbamates, phenoxy acids, triazines and oxime fungicides etc. in aqueous environmental samples have been developed.[96–98]

Unfortunately, TSP shows a number of experimental problems such as highly variable compound-dependent responses, the need for a critical control of relevant temperatures during analysis, thermal breakdown of labile analytes and the lack of structurally informative mass spectra. The last problem can be overcome by using liquid chromatography/tandem mass spectrometry (LC/MS/MS); identification can be achieved by using daughter ion tandem mass spectrometry (MS/MS) scans and collisionally induced dissociation (CID), most commonly on a triple quadrupole instrument. However, in comparison to LC/MS the instrumental cost of MS/MS systems are distinctly higher.

An important limitation encountered in both thermospray mass spectrometry (TSPMS) and particle beam mass spectrometry (PBMS) is the significant variation in sensitivity between the different classes of compounds or even for compounds from the same class. As regards this aspect, atmospheric pressure ionization (API) is most promising in combining high sensitivity and improved ionization stability by solving the problem of vaporized solvent entering the vacuum system of the mass spectrometer. API includes a group of interfaces usually addressed as electrospray (ES), ionspray (IS) and atmospheric pressure chemical ionization (APCI), which is the most flexible technique regarding conventional LC flow rates.

At present API interfaces are the most commonly used in LC/MS for target and nontarget analysis of pesticides from various matrices and the various mode applied in this field of analysis will discussed in more detail below.

4.2 Liquid Chromatography/Mass Spectrometry Methods

Volmer et al.[99] evaluated the use of LC/ESMS for multiresidue determination and confirmation of a large number of pesticides such as triazines, carbamates, phenyl- and sulfonylureas. Performing separation of analytes on 5 μm C_{18} column (150 × 3.2 mm ID) with a methanol–water gradient (20–95% methanol over 45 min) at 0.6 mL min^{-1}, post-column flow addition (0.4% formic acid in methanol, at 0.2 mL min^{-1}) and by means of splitting a 150 μL min^{-1} flow to the ESMS positive ionization (PI mode), time-scheduled single ion monitoring (SIM) yielded sensitive detection of most pesticides at the very low picogram level. Di Corcia et al.[100] developed a sensitive and specific method for the ultratrace analysis of atrazine and its major six metabolites in environmental water samples. The method makes use of SPE on cartridges packed with GCB followed by LC/ESMS. LC separation was carried on 5 μm C_{18} column (250 × 4.6 mm ID) with a gradient elution of methanol–water (both solvents contained 10^{-5} mol L^{-1} of formic acid) going from 0 to 84% methanol in 36 min. The flow rate of the mobile phase was 1 mL min^{-1}, and 40 μL of the column effluent was diverted to the ES source. Employing extraction volumes of 1 and 4 L of sample (river, ground- and drinking water) LODs of 3 ng L^{-1} were obtained (two-ion SIM acquisition) with a reproducibility of 2–7% and recoveries above 80%.

More or less the same approach concerning sample pretreatment and instrumental analysis was successfully applied by D'Ascenzo and co-workers[101] for the determination of five imidazolinone herbicides in various drinking water samples providing LODs of 2–5 ng L^{-1}.

The same group[102] developed an MRM for determination of 15 acidic herbicides (7 sulfonylureas, 4 imidazolinones, 4 aryloxyphenoxypropionic acids) in water by LC/ESMS in PI mode. A similar pretreatment procedure as mentioned above was used: passing of 2 L of groundwater and 4 L of drinking water samples, respectively, through a 0.5 g GCB extraction cartridge. A conventional 4.6 mm ID column operating with a methanol–water mobile phase (both solvents contained 10 mmol L^{-1} formic acid) at 1 mL min^{-1} was used to separate the analytes; from the column effluent, 200 μL min^{-1} were split to the ESI source. The very good performance of this approach is illustrated in Figure 21 showing total ion current (TIC) and time scheduled SIM chromatograms of the LC/ESMS analysis of a drinking water sample spiked with analytes at a level 25 ng L^{-1} each. The LODs calculated in SIM mode for drinking water were in the range of 0.5–4 ng L^{-1}. This method has also been applied to real groundwater samples in which imazathabenz, imazathabenz-methyl, haloxyfop, fluazifop and chlorsulfuron were found in concentrations ranging from 10 to 100 ng L^{-1}. Employing slightly different LC/ESMS conditions and SPE concentration on Porapak Rdx cartridges (Waters) comparable results were obtained for a group of 22 acidic pesticides of different classes when using SIM in negative ionization (NI) mode.[102]

The viability of off-line sampling of water samples on GCB cartridges and LC/ESMS towards multiresidue analysis of pesticides in environmental water samples is also illustrated by Crescenzi et al.[103] They developed a method for the determination of 45 base/neutral pesticides (carbamates, triazines, imidazole, phenylureas, anilides, triazoles, pyridazones) having a broad range in polarity. ESMS detection was optimized by adopting in-glass distilled methanol and 10 μmol L^{-1} TFA in water as mobile-phase constituents. For drinking water, LODs ranged between 1 (atrazine) and 9 (butoxycarboxim) ng L^{-1} from TIC chromatograms and were for most pesticides about 10 times lower when using SIM. The repeatability of the method of less then 10% for the analysis of an extract ($n = 7$) of a surface water sample spiked with the analytes at a level of 200 ng L^{-1}, emphasizes the ruggedness of the ESMS arrangement.

Figure 21 (a) TIC and (b) time scheduled SIM chromatogram of LC/ESMS (positive mode) of an extract of a drinking water sample spiked with the acidic herbicides at a level of $0.025\,\mu g\,L^{-1}$. Peaks: (1) imazapyr, (2) imazamethabenz, (3) triasulfuron, (4) thifensulfuron-methyl, (5) metsulfuron, (6) imazaquin, (7) imazamethabenz-methyl, (8) chlorsulfuron, (9) rimsulfuron, (10) tribenuron-methyl, (11) bensulfuronmethyl, (12) fluazifop, (13) fenoxaprop, (14) quizalofop, (15) haloxyfop. LC conditions: see text. (Reprinted with permission from D'Ascenzo et al., *Environ. Sci. Technol.*, **32**, 1340–1347. Copyright © 1998, American Chemical Society.)

The combination of a SPE cleanup on a GCB cartridge and LC/ESMS appeared also viable for the determination of 12 carbamate insecticides in fruits and vegetables to levels below $1\,\mu g\,kg^{-1}$ of crop.[104]

An intra- and interclass comparison of sensitivity, ionization and fragmentation for the determination of 17 pesticides in 5 chemical classes (triazines, phenylureas, organophosphorus, miscellaneous) in water with liquid chromatography/atmospheric pressure chemical ionization mass spectrometry (LC/APCIMS) was investigated by Doerge and Bajic.[105] Performing LC separation on a short C_{18} column (30×4.6 mm ID) with ACN–water mixtures at a flow rate of $0.5\,mL\,min^{-1}$ as the mobile phase the spectra obtained from most compounds consisted solely of $[M + H]^+$ in positive ion mode. Low nanogram LODs were observed for all compounds in scan mode and these were reduced to picogram levels by using SIM mode. For these diverse chemical classes variations in LODs were obtained of ca. 10-fold and 100-fold for scan and SIM mode respectively.

Barnes et al. developed LC/APCIMS based methods[106,107] for the determination of various pesticides in different types of foodstuffs. Diflubenzuron and clofentezine were determined in fruits employing a liquid organic solvent extraction and high-performance gel permeation chromatography (HPGPC) cleanup as sample pretreatment.[106] Applying RPLC with methanol–water (80 : 20; v/v) as the mobile phase ($1\,mL\,min^{-1}$) and atmospheric pressure chemical ionization mass spectrometry (APCIMS) in the PI mode, LODs were about $0.01\,mg\,kg^{-1}$. For the multiresidue analysis of 10 various pesticides (6 carbamates, thiabendazole, carbendazim, clofentezine, diflubenzuron) in fruits[107] samples were extracted with ethyl acetate. After solvent evaporation part of the diluted extract was directly processed with LC/APCIMS using PI/NI mode during each acquisition, which provided LODs in the range of $0.002–0.03\,mg\,kg^{-1}$ in the crop. The LODs obtained in the LC/APCIMS methods[106,107] clearly met the required MRLs for these compounds in foodstuffs. Despite the favorable features

it was observed that sensitivity is both compound- and matrix-dependent and will require next to solvent-based standards (check on column/instrument performance) additional calibration with matrix-matched standards.[107]

API applied in the LC/MS methods discussed above is a soft ionization technique that predominantly produces the protonated $(M + H)^+$ or deprotonated $(M - H)^-$ molecular ions in positive or negative mode, respectively. Increase in compound identification can be obtained by MS/MS based on detection of product ion(s) (daughter ions) formed by CID of the initially formed (de)protonated molecular ion (parent ion). For the determination of 22 acidic pesticides in water a comparison of LC/ES method performance by single MS and MS/MS was made employing a triple quadrupole instrument.[108] Despite a three-to four-fold decrease of the signal-to-noise ratio of analytes, the significant improvement in selectivity of MS/MS is clearly demonstrated in Figure 22 showing LC/ESMS analysis of a real-life groundwater sample containing three phenoxy acids at levels of about $10\,ng\,L^{-1}$.

The impressive improvement in selectivity of MS/MS was also demonstrated for the determination of imidazoline herbicides in soils.[109] This new class of low-use-rate herbicides must be monitored at low parts per billion levels, which could be achieved by using liquid chromatography/electrospray tandem mass spectrometry (LC/ESMS/MS).

4.3 On-line Liquid Chromatography/Mass Spectrometry Methods

Because of the possibility of automation, on-line procedures allow large screening and monitoring of environmental water samples. Therefore, besides or complementary to automated SPE/LC/UV/DAD systems the use of atmospheric pressure ionization mass spectrometry (APIMS) detection becomes more important in this field of analysis. The determination of 8 various types of acidic herbicides in environmental water was performed by automated on-line SPE on C_{18} cartridges and LC/MS using pneumatically assisted (or high flow) electrospray (PAES) for ionization in the NI mode.[110] The procedure required only 50 mL of water with LODs ranging between 10 and $30\,ng\,L^{-1}$ including the determination of the two major metabolites of bentazone.

SPE/LC (100 mL of sample) coupled to APCIMS, pneumatically assisted/electrospray mass spectrometry (PA/ESMS) and MS/MS detection was used for the trace analysis of a group of neutral pesticides (carbamates, phenylureas, triazines and organophosphorus) in water samples.[111] The interfaces provided comparable LODs for 15 pesticides (out of 17) in drinking water of $0.007–3\,\mu g\,L^{-1}$ and $0.1–200\,ng\,L^{-1}$ in TIC and SIM

Figure 22 LC/ESMS analyses of a SPE extract of a real-life groundwater sample containing chlorophenoxy acid herbicides at a level of about $0.010\,\mu g\,L^{-1}$. The sample was analyzed using (a) single MS in SIM and by (b) MS/MS in selected reaction monitoring mode. Peaks: (1) MCPA, (2) 2,4-D, (3) 2,4-DP. (Reprinted from Koppen and Spliid, 'Determination of Acidic Herbicides Using Liquid Chromatography with Pneumatically Assisted Electrospray Ionization Mass Spectrometry and Tandem Mass Spectrometry Determination', *J. Chromatogr. A.*, **803**, 157–168. Copyright © 1998 with permission from Elsevier Science.)

mode, respectively, with an analysis time of 65 min. NI operation was found to be less sensitive for the majority of compounds tested (73 in total). Both ionization techniques gave similar product ion spectra from protonated molecules and a MS/MS library was built for more than 60 pesticides and successfully applied for searching product-ion spectra at low levels (10 ng L^{-1}) in tap water.

The simultaneous analysis of a smaller and less heterogeneous group of pesticides, usually enhances sensitivity in LC/MS. A nice example is given in the study by Baltussen et al.[112] A sample volume of 10 mL appeared to be sufficient for the on-line LC/MS determination of five phenylurea herbicides in river water to a level of 10 ng L^{-1}.

High sensitivity/selectivity was obtained by on-line immunosorbent phase extraction and LC/APCIMS (PI mode) for the analysis of 8 triazine and 6 phenylurea herbicides in environmental samples.[113] Sample volumes of 20 mL of groundwater provided LODs in the range 1–5 ng L^{-1} For obvious reasons such as removal of early eluting interferences and protection of analytical column, on-line methods usually make use of column-switching (see above) for the trace enrichment of analytes on a SPE column (PC).

For the reduction of expensive measurement time of the LC/MS system the use of a single short column (SSC) for both trace enrichment and separation in combination with selective MS/MS detection is a powerful approach. The compromise between the minimum time of analysis and the minimum required chromatographic separation for a given application is determined by the efficiency of the column (total number of plates, n) which in turn will depend on the dimensions of the column and efficiency of the packing material. In fact, suitable conditions for sorption and desorption will always include a washing step (removal of inorganic salts) prior to elution, and minimum required separation between analyte(s) and solvent front in order to avoid the unstable ionization conditions caused by the rapidly changing elution solvent composition.

The viability of the SSC approach is shown by a number of methods involving the rapid determination of organic pollutants in water.[114–116] The first report on the SSC approach involved the use of a home-packed (5–8 μm C_{18} or 10–15 μm PLRP-S material) 10 × 2 mm ID column in combination with thermospray/tandem mass spectrometry (TSPMS/MS) for the on-line determination of triazines in surface water.[114] Unfortunately, stability-system problems related to the reproducibility and stability of the experimental column packings did not provide LODs below 10 μg L^{-1}. Improved results were obtained when using a 20 × 4.6 mm ID column high-pressure packed with 5 μm C_{18} combined with atmospheric pressure chemical ionization tandem mass spectrometry (APCIMS/MS).[115] For the set of 15 various pesticides analyzed before with SPE/LC, the SSC approach involving the processing of sample volumes as small as 15 mL resulted in LODs between 0.03 and 5 μg L^{-1} in full-scan mode and between 2 and 750 ng L^{-1} by SIM, both recorded in the positive ion mode. Further optimization of the use of SSC with APCIMS/MS involving ion-trap MS/MS instead of triple quadrupole MS/MS allowed the trace analysis of six triazines in less then 20 min by taking only 4 mL of sample and, hence, providing a high sample throughput. Unfortunately, sensitivity was not sufficient for the 8 phenylurea herbicides tested; this was probably caused by several current instrumental problems. SSC in the instrumental set-up including both diode-array UV and MS detection is an efficient approach in guarding microorganic pollution of surface waters. In these types of samples usually few or no microcontaminants are present allowing a degree of selectivity to be sacrificed by using less separation power in order to obtain a cost-effective procedure.[116]

5 LIQUID CHROMATOGRAPHY SAMPLE PRETREATMENT METHODS PRIOR TO GAS CHROMATOGRAPHY

The availability of techniques, nowadays, to perform large-volume introduction GC,[117] has made the combination of LC and GC more accessible. As a result, one can easily combine the advantageous features of LC such as on-line trace enrichment and/or cleanup with the high separation power and selectivity/sensitivity of capillary GC.

Based on the type of sample/extract and the type of mobile phase, that is an aqueous solvent or an organic solvent, one can discriminate two different modes in LC methods used in combination with GC.

The LC mode employing organic solvents is focused on the efficient cleanup between macromolecules such as fatty substances (triglycerides) or plant material (chlorophyllic) and pesticides. In these types of separations GPC and NPLC are used because of their high degree of automation. The other LC-mode is based on coupling SPE columns to capillary GC providing on-line analysis of pesticides in environmental water samples.

Methods involving these LC modes will be briefly discussed below.

5.1 Gel Permeation Chromatography and Normal-phase Liquid Chromatography

For the determination of apolar pesticides with accumulating properties in fat, e.g. organochlorine pesticides, the first step is the isolation of the fat from the fatty

matrix. Usually this is done by extraction with an organic solvent yielding an extract in which the fat has to be separated from the analytes. As regards vegetable, human and animal fat, cleanup will be focused on the separation between pesticides (low-molecular-weight compounds) and triglyceride-esters (high-molecular-weight compounds).

Two powerful LC-based fully automated approaches are available using either GPC[1,118–124] or NPLC silica cleanup[125–129] to perform the separation between the fatty compounds and the pesticides. GPC is applied most frequently since its separation, based on molecular mass, results in the widest scope concerning both matrices and analytes.[1,118,119] The availability nowadays of HPGPC columns packed with small size particles (7–10 μm) providing small elution volumes of analytes,[121–124] typically 100–300 μL, allows the coupling of GPC to GC allowing automated procedures.[123,124]

The advantage/disadvantage of the NPLC silica cleanup approach is that the high separation power of analytical column packed with 5 μm silica favors selective cleanup but counteracts the range in polarity of analytes.[125–128] Productive methods have been developed for monitoring of organochlorine pesticides in milk[125] and various types of fatty matrices[126,127] and 1,1-dichloro-2,2-bis(4-chlorophenyl)ethane (DDE) and polychlorinated biphenyls (PCBs) in extracts of adipose tissues[128] employing NPLC off-line[125,126] or on-line,[127,128] respectively. For the determination of the more polar organophosphorus pesticides in mussels the separation between analytes and fat was successfully carried with NPLC by collecting the analyte in a fat-free fraction using different mixtures of hexane–ethyl acetate.[129]

5.2 Solid-phase Extraction Combined On-line with Gas Chromatography

The coupling of SPE to GC provides fully automated procedures for the determination of pesticides in environmental water samples. Small volumes of sample, typically 1–5 mL, are sufficient to obtain the required sensitivity. PCs (10 × 2 mm ID) packed with 15–25 μm PLRP-S copolymer have been used for the on-line determination of nitrogen- and phosphorus-containing pesticides in water at the low nanogram per litre level.[130–132] This PC material shows favorable properties for the required solvent-phase switch involving (i) adsorption of analytes during sampling, (ii) the removal of water by passing nitrogen and (iii) desorption of pesticides with an organic solvent, e.g. ethyl acetate.

An automated ''off-line'' SPE system (ASPEC) has been coupled to GC with electron capture detection (ECD) for the on-line analysis of pyrethroid insecticides in water.[133] This approach combines extraction and cleanup by adding 30% of modifier (methanol) to the water sample prior to SPE on a 100 mg C_{18} cartridge and a washing step of 1 mL of 30% methanol in water. After drying with air, the cartridge is eluted with 1.5 mL of toluene. GC analysis with ECD and on-column introduction of 100 μL of the extract provided LODs in the range of 1–8 ng L^{-1}.

6 CONCLUSIONS AND TRENDS

LC has proven to be an efficient technique in PRA making it very complementary to GC for the determination of polar and/or thermolabile pesticides. LC methods cover samples from both the disciplines of public health and environmental protection and the column switching mode easily provides semi- or fully automated procedures including on-line cleanup and/or trace enrichment. Future developments in LC will be focused on the enhancement of sample throughput, robustness, scope of analytes, selectivity, sensitivity and, even more importantly, reduction of cost.

Providing high selectivity/sensitivity for the determination of pesticides with widely different (physicochemical) properties, RPLC combined with APIMS is a powerful and attractive technique, and increasing use in this field of analysis can be expected. Especially in studies on the identity and concentration of formed TPs, always more polar then the orginal pesticides, LC/MS will be a highly desirable technique.

Despite the high selectivity of MS or MS/MS combined use with column switching techniques, viz. SPE/LC or LC/LC, can be attractive in order to eliminate matrix-dependent quantification of analytes in the processing of uncleaned extracts.

In comparison to conventional LC, capillary LC offers a number of favorable features such as reduction of solvent consumption, improvement of sensitivity and interfacing to more selective and sensitive detectors. Because of the susceptibility of the technique to clogging/contamination problems caused by the excess of matrix interferences the use of capillary LC in PRA is still limited. Here, column switching appeared to be favorable to enhance sample load and cleanup as shown for the coupling of capillary LC to infrared spectrometry for the unambiguous identification/determination of medium polar pesticides in surface water at the 2–5 μg L^{-1} level.[134]

An interesting development in obtaining high selectivity is the on-line coupling of RPLC and high-performance thin-layer chromatography (HPTLC) in the normal phase mode.[135] This two-dimensional low-cost separation system offers high peak capacity, an attractive feature in PRA.

In this article, a detailed overview of the current high-performance liquid chromatography/mass spectrometry (HPLC/MS) instrumentation, suitable for the determination of a large number of pesticides, is reported. Particular emphasis is given to the role of the mass spectrometric apparatus involved in each interfacing technique with several types of information regarding the ionization processes, analyzer principles and system configurations. The article gives an up-to-date picture of the current instrumentation that is available and readers will find only brief references to some important historical approaches that are no longer in use.

1 INTRODUCTION

Can mass spectrometry (MS) do for high-performance liquid chromatography (HPLC) what it does for gas chromatography (GC)? This is probably the question that many analytical chemists, biochemists and pharmacologists asked themselves while arguing in front of their ultraviolet (UV) chromatograms. In fact, the use of an ultraviolet/visible (UV/VIS) spectrophotometric detector, which is the most widely used detector for liquid chromatography (LC), is restricted in sample selectivity by the sensitivity in a particular absorption band. Other detectors, such as fluorimetric or electrochemical, are even more limited and rarely employed. When compared with GC, for which a variety of excellent detectors are available, HPLC detectors cannot meet the demand.

MS is the most specific technique for the detection and identification of organic compounds. MS can provide not only molecular weight information but also a wealth of structural details that together give a unique fingerprint for each analyte. MS is the detector with by far the highest information output per unit sample weight. The dynamic combination of gas chromatography/mass spectrometry (GC/MS) has yielded the most specific and sensitive method for the characterization of the components of complex volatile mixtures.

Under this circumstance, the use of a mass spectrometer as an HPLC detector has been widely investigated. Since the majority of all known compounds are amenable to HPLC, the integration of HPLC and MS greatly extends the range of compound classes that can benefit from the particular characteristics of MS detection. With uninterrupted evolution over the last 25 years, it has produced amazing results for both chromatographers and mass spectrometrists to the point that HPLC/MS represents one of the most important tools in the characterization of all organic compounds. Unfortunately, while the evolution of the coupling of GC and MS has led to a single, relatively simple and inexpensive device, progress in HPLC/MS interfacing, far more challenging than that with

GC/MS, generated several highly developed interfaces with radically different designs. The reason for the complexity of HPLC/MS is that the domains of LC and MS are often seen as antagonists: the effort of achieving and maintaining the high vacuum required for MS operations conflicts with the intrinsic nature of LC, predominantly operating at high solvent flow rates. In addition, the low tolerance of mass spectrometers to nonvolatile mobile phase components contrasts with the LC dependence on nonvolatile buffers to achieve high-resolution separations. In the effort to overcome a series of evident difficulties, HPLC/MS interfaces use different strategies and, as consequence, they are usually expensive and complicated compared with the intrinsic simplicity of GC/MS.

Difficulties in HPLC/MS can be summarized by the following two points:

1. *Solvent restriction*: an HPLC mobile phase (solvent) is a liquid, and sample components are led to the detector together with the solvent. Because a high vacuum is required during MS operations, not much solvent should enter the MS when it functions as a detector. If the HPLC flow rate is $1\,mL\,min^{-1}$ (liquid) and the mobile phase is water, the gas volume generated in the mass spectrometer is as large as $1200\,mL\,min^{-1}$!
2. *Sample restriction*: LC analyzes all samples that can be dissolved in solvents. The analytes may vary dramatically in weight, polarity and stability and this poses a severe restriction in terms of hardware requirements for both the interface and mass spectrometer.

In this article, recent developments in the use of HPLC/MS methods in the analysis of pesticides are outlined. Particular attention is devoted to the various interfacing techniques currently used in this field, such as thermospray (TSP), electrospray (ES), atmospheric pressure chemical ionization (APCI) and particle beam (PB). A selection of the mass analyzers normally used in conjunction with HPLC/MS interfaces is also considered. In the discussion regarding the performance of the various systems, sensitivity, detection limits, response linearity and other parameters are critically evaluated.

2 INSTRUMENTAL PARAMETERS INVOLVED IN PESTICIDE ANALYSIS

A number of parameters are particularly useful to the analyst in selecting the most appropriate HPLC/MS system to identify and quantify the analytes, depending on the chemical properties and complexity of the sample. Far from being exhaustive, we feel that the criteria described below are particularly important for evaluating the alternatives to accomplish the needs when performing pesticide analysis.

2.1 Mass Range

The difference between the upper and the lower limits of the mass-to-charge ratio (m/z) is called mass range and defined according to Equation (1):

$$\Delta m_{\text{range}} = m_{\text{upper limit}} - m_{\text{lower limit}} \tag{1}$$

Depending on the mass analyzer, the mass ranges can span from 500 to 3000 for a quadrupole or an ion trap to no upper limits for a time-of-flight (TOF) mass analyzer. Since the molecular weight of most pesticides is <500, the higher cost of an extended mass range is not required.

2.2 Mass Resolution

Mass resolution is the capability of a mass analyzer to resolve one mass from the adjacent mass and is described by Equation (2):

$$R_{\text{m}} = \frac{m}{\Delta m_{\text{resolution}}} \tag{2}$$

where m is the measured mass and $\Delta m_{\text{resolution}}$ is the difference between two adjacent mass peaks. A resolving power of 100–1000 (1000–2000) is typical of low-resolution analyzers such as quadrupoles and ion traps and implies unit resolution. This mode of operation is particularly convenient when using HPLC/MS, since possible interferences can be removed chromatographically. The advantage offered by electron ionization (EI) is that the acquired spectra can be compared with those in libraries for the fast identification of unknown compounds. This interesting feature is currently available only with a PB interface. TOF analyzers can operate at both low and high resolution. Sectors operate at high resolution for accurate mass measurements with a resolving power of 5000–10 000. This allows the separation of more than one analyte with the same nominal mass and it represents an unsurpassed tool for the determination of elemental composition. It is particularly important to determine the increasing presence of pesticides and their metabolites in the environment. The performance of a sector can be enhanced, providing additional specificity, when more than one analyzer is placed in series either in four sectors or a hybrid configuration. On the other hand, the cost and the operating skills required for such an instrument are elevated. Triple quadrupoles and ion traps allow mass spectrometry/mass spectrometry (MS/MS) configurations at a lower price with competitive sensitivity.

2.3 Spectral Characteristics

The characteristics of a mass spectrum can vary widely, depending on the ionization technique, interface and analyzer used. Highly informative, fragmentation spectra are needed in those applications where structural elucidation and identification are under investigation. Fragmentation spectra are obtained when electrons coming from a hot filament (EI) ionize the analyte molecules. The PB is the only interface that provides fragmentation spectra in single analyzer configuration on both quadrupole and sector analyzers. Collisions within the interface [source–collision-induced dissociation (CID)], available with ES, or tandem mass analyzers (MS/MS) can be used to obtain fragmentation spectra.

It has been demonstrated that even polar or ionic pesticides can be analyzed under EI conditions.[1] In this case and when the molecular ion intensity is too low, alternative ionization techniques can provide simple spectra containing the molecular ion. This is the case with APCI, ES and TSP. CID can provide additional structural information.

2.4 Limits of Detection

When performing pesticide analysis, one should keep in mind their extremely low concentrations in the matrix and all the possible interferences. Selectivity can be achieved in any of different steps of the analysis, from sample preparation to the different alternatives of liquid chromatography/mass spectrometry (LC/MS) equipment. Instrument noise can originate either from the components of the system or from the chemical background and may severely complete with the very low signal of the analyte at ultratrace levels. APCI, ES and TSP allow the detection of most pesticides at the picogram level, whereas PB is less sensitive, with detection limits in the range of nanograms. Improving the detection limits depends not only on the interface and ionization technique chosen, but also on the analyzer and on the analyzer configuration in the case of MS/MS. With the latter, increasing the signal-to-noise ratio allows the detection of extremely low concentrations of substances.

2.5 Universality

When dealing with complex mixtures or real samples, it is very welcome to count on an instrument that can respond to all components, especially when unknown molecules need to be characterized. This is particularly true in pesticide analysis when metabolites or adducts need to be characterized. Universality is in this case a fundamental requirement to guarantee the complete identification and quantification of the sample components. Once again, one can play with the selectivity to restrict the field of interest. The polarity of the molecule plays a major role in choosing the ionization technique. EI is *the* universal ionization technique for nonpolar, polar nonionic and ionizable substances. The use of EI is limited to the PB, but this does not represent a limit in pesticide analysis since the molecular weight of most pesticides is far lower than 600 u. ES is preferable with ionic compounds and APCI and TSP produce a very good response with polar nonionic and ionizable compounds.

3 HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY COUPLING TECHNIQUES

3.1 Introduction

In its infancy, HPLC/MS was considered as an adaptation of GC/MS towards thermolabile molecules carried by a liquid medium. In the mid-1970s, EI was like a flagship for MS. A reliable, reproducible, library-matchable EI spectrum was the key for a winning GC/MS technology, so its adaptation to a vaporizable eluate was considered a valid approach for the emerging LC/MS 'hyphenation'. At that time, the extension of the analyzable mass range was limited and so was the mass range of the analytes convertible into the gas phase. The HPLC eluate was therefore forced into a classical EI ion source directly or through a mechanical adapter. The first case, called direct liquid introduction (DLI), was first developed by Baldwin and McLafferty[2] and consisted in direct vaporization and ionization of a split HPLC column effluent. The reduced flow rate ($10–50\,\mu L\,min^{-1}$) allowed normal MS operation but, because of the solvent vapor residues, imposed chemical ionization (CI) as the only ionization choice. Simplicity was good but the sensitivity was only acceptable and did not match the performance of GC. The mechanical alternative to DLI into a conventional EI/CI source was the moving belt interface.[3] This innovative interface consisted of an auxiliary vacuum chamber through which a Kapton moving belt carried the column eluate and evaporated the solvents. The dry solutes were carried into the ion source, vaporized and ionized. After a cleaning process, the belt was ready for a new cycle. Solvents were removed completely and EI was achievable. Major drawbacks were related to the mechanical complexity of the interface, loss of chromatographic resolution and memory effects on the reused belt. Both interfaces were abandoned and were replaced by the much more efficient and reliable PB interface. The PB interface, first developed as monodisperse aerosol generator (MAGIC) LC/MS[4] to underline the monodisperse aerosol mechanism through

which the liquid effluent is introduced into the ion source, is the best EI-based LC/MS interface currently in production.

LC/MS interfacing has also introduced a new concept: the integration between coupling mechanism and sample ionization in one combined process. This innovative approach opened the way to new 'soft' ionization techniques, namely TSP, fast atom bombardment (FAB), and atmospheric pressure ionization (API), which have revolutionized MS with their ability to ionize high-molecular-weight molecules and, in some cases, allowing the detection of picograms or less of material. These techniques, producing poor or no fragmentation of the analytes, with the absolute predominance of the molecular ion in the mass spectrum, have their best attribute in a higher sensitivity for several compounds. Differently from EI spectra, which reproduce what was in the original sample, API encumbers interpretation with artifacts that were not present in the sample (adducts, polymers, etc.). For instance, aldicarb only produces significant $[M + Na]^+$ without a molecular ion $[M + H]^+$, which could cause difficulty for a novice. In addition, there is no capability for commercial library identification of unknowns or 'unsures' in the hands of novices. The lack of typical EI information capability was partially compensated by a contemporary evolution of high-performance, coupled MS analyzers (MS^n) that, although complex and expensive, ensured a valid identification criterion for the target compounds. The family of soft ionization techniques, readily embraced by protein chemists for their high-mass capabilities, were slowly converted also to the detection of low-mass analytes at ultratrace concentrations. Only FAB ionization, which opened the way for the use of MS in biomedical applications, was rarely applied to samples of environmental concern.[5]

In conclusion, whatever the interface principle being used, it must be subject to three conversion processes, always required when LC is coupled to MS:

1. An *evaporation process* is required to convert the analyte from a liquid phase to a rarefied gas phase.
2. A *pressure-reduction process* is required to convert the analyte, separated at atmospheric pressure, into high vacuum for mass analysis.
3. An *ionization process* is required to convert an often-neutral sample into detectable ions.

The occurrence of the three processes may vary in sequence in the various interfaces but they must be always present. On this basis, two groups can be highlighted: the API and TSP interfaces, in which the ionization step precedes the vacuum conversion, and the rest of the interfaces in which the ionization occurs at high vacuum.

Figure 1 Domains of application of LC/MS interfaces.

Daring combinations of up-to-date ionization techniques and advanced analyzers keep the LC/MS market very unpredictable but arguably, API and PB (TSP having largely been superseded by APCI) are now well established to be considered as the foundations for future interface developments.[6] Figure 1 illustrates the domain of each interface with respect to GC/MS.

3.2 Thermospray

The TSP interface (Figure 2), developed in 1980 by Vestal et al.,[7] was one of the first attempts at LC/MS techniques using soft ionization. A TSP interface addresses two fundamental problems: it reduces the pressure of the residual HPLC solvents into the mass spectrometer and self-generates ions of the analyte. Both results are obtained by applying heat to the incoming HPLC eluate.

Figure 2 Schematic diagram of TSP interface. (Reproduced from Blakely et al.[7] with permission from John Wiley & Sons Inc.)

The liquid effluent is forced into a heated capillary tubing that ends inside a heated desolvation chamber. The heat vaporizes the liquid while it travels through the interface and the majority of the solvent vapor is removed by an auxiliary vacuum pump placed at the end of the path. Only a small fraction of vapor is admitted into the mass spectrometer through a small orifice in the chamber, thus achieving the required pressure-reduction step. When properly controlled, the TSP interface is capable of accepting aqueous HPLC effluents at rates up to $2\,mL\,min^{-1}$.

Nonvolatile molecules are retained inside the aerosol droplets while they diminish in size during the vaporization process. An electrolyte, added to the HPLC mobile phase, produces an initial electrostatic field on the droplet surface and, in a way that resembles ES ionization, promotes the analyte ionization: the rapidly desolvating charged droplets increase the surface field while diminishing their size, until the point at which the charged analytes are ejected into the vapor stream. Ions are extracted from the desolvation chamber and accelerated toward the mass analyzer. Ammonium acetate can be added postcolumn and is capable of enhancing ionization of target analytes.

TSP produces molecular and adduct ions of the nonvolatile analyte with poor fragmentation. Molecules that are neutral in solution may produce $[M + H]^+$ ions during the TSP process while adding postcolumn ionic additives to the HPLC mobile phase can generate negative ions (NIs). A filament, producing gas-phase electrons, can be added to the chamber, inducing CI reactions with the solvent used as the reagent gas.

TSP is limited by the use of aqueous mobile phases. Lack of structural information is not compensated by higher sensitivity, which is two orders of magnitude lower than in ES. TSP may produce more fragmentation than FAB but is not comparable to the superior identification capability of PB that shares the same applicability. TSP shows its best attribute for ionic and polar compounds with molecular weights <2000 u.

3.3 Electrospray

ES[8,9] has revolutionized MS with its ability to ionize high-molecular-weight molecules and detect even femtogram levels of material. The ES LC/MS interface relies on the API technique for ion generation. Similarly to TSP, the ionization of the analytes takes place into fast evaporating liquid droplets but, instead of using an electrolyte and a high temperature, an electric potential is applied to the incoming HPLC effluent at atmospheric pressure (Figure 3).

The intrinsic simplicity of the ES design makes it a successful tool for LC/MS interfacing. A strong electric

Figure 3 Schematic diagram of ES interface.

field (2–4 kV) is applied between a hollow needle, through which the HPLC effluent emerges, and a collector. The high field at the tip of the needle produces a cone-shaped liquid meniscus from which a spray of highly charged droplets is formed. During their travel from the needle to the collector, the droplets evaporate while diminishing their size, thus allowing the electric charge to concentrate at the droplet surface. At this point, a prerequisite for the final gas-phase ion generation is that the analyte exists as an ion in solution or could be easily ionized through a charge transfer when still in solution.[10] If a species is present with more than one ionizable site, then ES will also produce more than one charge in the gas-phase ions. The benefit is evident with high-molecular-weight substances where the multiple charged ions, generated by ES, shrink the mass spectrum into the mass range of a typical mass analyzer. The charge concentration, observed during the droplet evaporation, weakens the natural solvent cohesion up to the point at which electrohydrodynamic disintegration into many smaller droplets occurs. This mechanism ends when the droplet size reaches the Rayleigh limit (the point at which repulsive forces overcome the cohesive forces of the solvent) and eventually it results in the expulsion of the ionized analyte into the gas phase. This ion evaporation process is believed to be the major mechanism for ionizing smaller molecules.[11]

At atmospheric pressure, the solvated ions pass the collector and, following their momentum, travel toward the analyzer. A gas curtain (usually nitrogen at 1 Torr pressure), placed between the collector and the vacuum region, impacts the incoming ions quickly removing the last solvent molecules and generating low-internal-energy quasimolecular ions. In fact, the energy of those impacts, controlled by electric potential applied to the needle, can be a useful source of CID spectra of the analyte.[12] The CID spectrum, generated in the ES region, is qualitatively similar to the spectrum recorded on a tandem MS instrument and can provide

Figure 4 Full-scan background-subtracted spectra taken from the average of the peaks for (a) butocarboxim, (b) carbaryl, (c) primicarb and (d) mercaptodimethur acquired by on-column injection of 5 ng each of the analytes. (Reprinted with permission from A. Di Corcia et al., *J. Agric. Food Chem.*, **44**, 1930 (1996). Copyright 1996 American Chemical Society.)

the structural information necessary for the analyte confirmation (Figure 4).[13] However, the ion pattern does not show the high reproducibility of that with typical EI. Unlike the analysis by tandem MS, where the ions are separated before CID, in a source CID the isolation of any analyte ion relies only on the LC separation. ES is also very susceptible to the chemistry of solutions and all the equilibria involved may affect the final sample result.

Conventional ES usually operates between 1 and $10\,\mu L\,min^{-1}$. Pneumatically assisted aerosol generation [ionspray (IS)] allows the use of higher flow rates.

3.4 Atmospheric Pressure Chemical Ionization

ES ionization is best suited for high polar species or molecules with an acidic or basic site. An alternative for less polar molecules is APCI.[14] APCI relies on an API interface as in ES, but produces the ions directly in the gas phase after the solvent and solute have been completely evaporated. In order to promote vaporization, the HPLC eluate, at a flow rate of $0.5–2\,mL\,min^{-1}$, is converted into an aerosol and rapidly heated to 450–550 °C inside an ionization chamber. Ionization is accomplished with a source of electrons addressed on-axis with the heated spray. The electrons are usually supplied by a corona discharge source but a ^{63}Ni emitter can also be used. A plasma of reagent ions is produced at atmospheric pressure in the ion source by EI of source gases and solvents. At this pressure the chance of interactions between reagent ions and analyte molecules is very high and protonated ions are normally generated. The mass range is limited compared with ES but the applicability of APCI is wider, spanning from ionizable to nonpolar compounds. ES and APCI can be configured on the same instrument, enhancing the problem-solving capabilities of both.

3.5 Particle Beam

The PB interface[15] can be considered as the liquid-phase counterpart of a GC/MS interface. Its design is not new but, differently from other attempts, survived the tough competition with the emerging API techniques and now plays a key role in the solution of several problems. The PB can be considered as a 'transport' interface in which the majority of mobile phase solvents are removed and the analyte is transferred into the mass spectrometer for the final ionization. The breakthrough of the PB interface is represented by the conversion of the HPLC effluent into an aerosol of high-surface-area droplets and, after a rapid evaporation, into a beam of solute particles. Even though the development of PB took advantage of several detailed implementations involving different aspects of its functioning,[16] it still relies on three key components (Figure 5): (1) aerosol generator, (2) desolvation chamber and (3) momentum separator.

The production of a fine spray can be accomplished by either a pneumatic or a thermal aerosol generator designed to accommodate mobile phase flow rates up to $0.5\,mL\,min^{-1}$. A dispersion gas, usually helium, is driven coaxially to the liquid jet. A capillary-scale version of the interface enhances the overall performance at mobile phase flow rates of only a few microliters per minute.[17] The atmospheric pressure desolvation of the aerosol droplets produces a mixture of dispersion gas, solvent vapors and solute particles, but only the last (the high-momentum fraction) reaches the ion source, the rest being

Figure 5 ThermaBeam LC/MS interface and vacuum chamber processes. (Reproduced by permission of Waters Corporation from *Waters ThermaBeam Mass Detector Installation Manual*.)

removed in the momentum separator. This effective and simple interfacing approach relies on a classical EI/CI ion source and generates reproducible, library-matchable spectra for easy compound identification. This is ideal for those applications where structure information for small (<1000 u), HPLC-amenable molecules are needed. Even though picogram-level sensitivity is hardly achieved, PB plays a unique role in the world of HPLC/MS interfaces.

4 MASS ANALYZER ALTERNATIVES

4.1 Introduction

A mass analyzer represents the heart of a mass spectrometer. Choosing among different mass analyzers is necessarily the first move and should precede any other consideration when approaching MS. They all do basically the same job, some just do it better than others and at a different cost. Mass analyzers come in a variety of shapes and sizes but they all require three conditions without which ion detection would be impossible: (1) high vacuum, (2) charged analytes and (3) gas-phase ions.

Besides these common features, mass analyzers differ significantly. They all use a combination of electric or magnetic fields or both in order to separate the ions in space or time. Each analyzer may excel in mass resolution, extension of the mass range, detection sensitivity or scan speed. Some of them may include the possibility of generating MS/MS or MS^n ($n = 1, 2, 3, \ldots$) spectra following a high- or low-energy CID event. All of them are suitable for coupling with chromatography but at a different cost and with different results. In conclusion, as highlighted in Table 1, where a comparison among the most common analyzers is reported, each one should balance advantages and limitations in order to suit better the LC/MS needs.

4.2 Quadrupole

A quadrupole mass analyzer, as its name implies, consists of a set of four parallel electrodes with either a circular or hyperbolic cross-section. The electrodes, placed at

Table 1 Key characteristics of different MS analyzers

Mass analyzer	Separation principle	Ion production	Resolution	Mass range (u)	Scan speed ($u\,s^{-1}$)
Quadrupole	Electric field (filter)	Continuous	Low	3000	4000
Ion trap	Electric field (stability)	Pulsed	Low	3000	4000
TOF	Electric field (velocity)	Pulsed	Low (or high)	Unlimited	10^6
Sector	Magnetic field (filter)	Continuous	High	20 000	Slow

the four angles of a square, are charged with two voltage components: a direct current (DC) and an alternating current (AC) oscillating in the radiofrequency (RF) range. Opposing sets of rods share the same voltage pattern but are charged with a different polarity (Figure 6). The electric field created in the space delimited by the four rods is called the quadrupole field. The quadrupole field shows some peculiar characteristics that can influence the path of a moving charged particle. When the quadrupole field is placed between the ion source and the detector, the stability of the ion trajectory is directly related to the RF/DC voltage ratio applied to the electrodes so that only a specific m/z value is allowed into the detector for a given voltage ratio. By ramping the electrode voltages, but keeping the RF/DC voltage ratio constant, a complete range of masses can be passed to the detector and the mass spectrum recorded. Therefore, the quadrupole analyzer is basically a mass filter whose mechanism can be explained by the superimposition of a high-pass mass filter and low-pass mass filter. The positively charged rods permit the transmission of all the ions above a critical m/z value while the negatively charged rods permit the transmission of those ions below a certain m/z value. The overlapped region created by the two filters forms a band-pass for a specific mass-to-charge ratio whose width can be varied by altering the RF/DC voltage ratio of the opposite sets of rods. Mass resolution is directly related to this bandwidth but it usually remains low (1000 at m/z 1000). The mass range is also limited, often being lower than 1000 u, but in some cases it can be extended up to 4000 u. This limit can be easily overcome when an ES LC/MS interface is in use.

A quadrupole analyzer is less costly than other analyzers and permitted the wide diffusion of MS detectors among the chromatographic community. Today, the quadrupole can be coupled to HPLC by the means of any available interface. Its typical sturdiness and reliability make it the optimum choice for high-throughput applications where dirty samples and high backgrounds may affect the quality of the results. It has evolved also as a tandem analyzer (MS/MS) in a configuration known as a triple quadrupole. The third quadrupole is an RF-only system and for its characteristics is used as collision region for CID experiments. Quadrupoles are also used in hybrid mass spectrometer configurations in which different analyzers are coupled together.

4.3 Ion Trap

The ion trap analyzer is very close in principle to a quadrupole analyzer in which the positively charged rods are bent and joined together to form a donut-shaped electrode (ring electrode) and the remaining set of rods are transformed in two hemispherical electrodes placed above and below the donut (end-caps). This configuration (Figure 7) is called a quadrupole ion trap. The similitude does not end here: in fact, as in the quadrupole analyzer, an RF oscillating voltage is applied to the ring electrode

Figure 7 Schematic diagram of ion trap mass spectrometer. (Reproduced by permission from J. Throck Watson, *Introduction to Mass Spectrometry*, 3rd edition, Lippincott-Raven, New York, 1997, 81.)

although, differently from a quadrupole, a DC potential is not required. The end-caps can be charged with a ground, DC or AC potential. While the quadrupole analyzer is basically a mass filter that temporarily traps the ions into a two-dimensional space only during their stable trajectory inside the quadrupole field, the ion trap analyzer forces all the ions together in three-dimensional space inside the trap until, depending on their m/z value, they are ejected towards the detector. The extraction of the ions from the trap is m/z specific and is obtained only when an RF potential is applied to the end-caps. A full mass spectrum of the analyte is recorded by ramping the ring electrode potential. As the ring electrode potential changes, the frequency of the ion stability also changes until the end-cap frequency matches the resonance frequency of an ion. All the ions sharing the same mass-to-charge ratio become excited into an expanding oscillating motion up to the point at which they are expelled from the trap. The mass resolution is comparable to that of a quadrupole analyzer and is obtained confining the ions with a given mass-to-charge ratio in similar spatial position inside the trap volume. A buffer gas such as helium, admitted into the trap at a pressure of 10^{-3} Torr, promotes this process by cooling the kinetic energy of the ions. This process reduces time dispersion when the ions are expelled for recording.

The trapping principle is highly efficient especially when compared with a quadrupole analyzer where all the ions, except those with a specific mass-to-charge ratio that reach the detector, are wasted. This may generate, in theory, very sensitive full spectra not far from the typical selected ion monitoring (SIM) performance. Unfortunately, the ion accumulation process cannot proceed indefinitely since the spatial focusing of the trap may promote space-charge disturbances among too close oscillating ions, with loss of resolution and errors in mass scale calibration. Thus, ion access to the trap is pulsed and an automatic gain controller (ACG) regulates their admission from an external ion source. It is noteworthy that samples that give good results in a quadrupole instrument may be too concentrated, by one or two orders of magnitude, for ion trap MS. In an ion trap analyzer, MS/MS experiments are spaced sequentially in time instead of space. The precursor ion is kept in place by applying an RF potential on the end-caps and selectively ejecting the remaining ion from the trap. A resonating frequency that corresponds to the isolated mass is then applied to the end-caps, causing the precursor ion to increase its oscillation. After numerous collisions with helium atoms, product ions are generated and recorded. Instead of recording all the fragment ions, a new precursor ion can be selected and with a new sequence of operations MS^n experiments can be performed.

4.4 Time-of-flight

The TOF mass analyzer is, in principle, very simple, being based on the fact that ion velocity is mass dependent. A 'linear' TOF consists of an ion source, a field-free flight tube and a detector. As soon as the ions are generated in the ion source they are accelerated along the flight tube by a burst of electric potential. For every pulse a group of ions will acquire the same kinetic energy and will start at the same time. Based on this fact, each mass entering the flight tube has a different velocity: the ions of lowest mass have the highest speed. The initial group of ions will separate as they proceed along the flight tube and arrive at the detector at different times. Hence, the arrival time is directly related to mass or, in this case, m/z. In this configuration though, a TOF instrument shows a poor mass resolution ($\sim$1000 at m/z 1000). Two factors are responsible for this effect: variable ion formation time and different initial velocity. Both factors will cause ions, of the same mass, to have different arrival times at the detector. A common variation of TOF, which allows a consistent improvement of the mass resolution, incorporates an electrostatic mirror (reflectron) into the field-free region to compensate for energy differences at the start. This field reflects the ions in a position close to the ion source where they are detected. The fastest ions, with the same mass-to-charge ratio, penetrate deeply inside the reflectron field before being reflected. The longer path to the detector is covered in the same time as the slower ions, thus increasing mass resolution.

TOF has characteristics that are ideal for structural elucidation problems, namely high sensitivity in the scan mode and high scan speed. The last feature makes it a valid contender for high-speed GC/MS applications and a sensitive detector for full-scan acquisition. It is noteworthy that SIM acquisition, although possible, does not improve the analyte response, the relative signals being extracted when all the ions have already been collected. Recent technology developments have also added high resolution and high mass accuracy to the list of TOF capabilities and it often used as second analyzer in MS/MS instruments (Q-TOF, EB-TOF, etc.). Newer Q-TOF instruments are appearing with a resolution of 15 000.

4.5 Sector

A sector analyzer is usually referred to as a sequence of electrostatic and magnetic fields located along the ion path with the purpose of selecting a highly resolved isomass beam (same m/z value). Sector instruments have been always considered the reference for high-performance, high-resolution MS, but their cost and complexity have often confined MS into an elitist club.

In a sector instrument, the ions, accelerated from the ion source at a voltage of 4–8 kV, are deflected in a circular trajectory inside a strong, sector-shaped magnetic field (B) (Figure 8). The radius of the trajectory is m/z dependent, being created by the balance between the centripetal Lorenz force and the ion momentum, so that ions of various mass-to-charge ratios are separated in space and exit the sector at different positions. The ion detector is located at the end of a single ion beam whose value depends on either the magnetic field or the accelerating potential. These fields can be varied opportunely for mass spectra recording. In this simple configuration, the mass resolution is heavily affected by the thermal energy dispersion at the moment of the ion formation. In order to increase the mass resolution power of the instrument, a second radial electrostatic sector (E) is added on the ion beam path before or after the magnetic sector, thus creating a variety of tandem configurations. In the electrostatic sector the energy dispersion of the ions is converted into a spatial dispersion of isomass ions at different velocities. Then, entering the magnetic field in different positions, the ions undergo compensating deflections with a final refocusing of the beam. Sector instruments separate ions simultaneously but, since only one beam is allowed to the detector, no more than one species can be collected at a time. A multichannel array detector allows simultaneous detection over a larger area, collecting several ions at the same time.

Sector MS is still the instrument of choice when high-resolution ($R \leq 100\,000$) mass spectra are required. MS/MS operations, either with a four-sector (EBEB, BEBE) or a hybrid configuration (EBQQ, BEQQ and BE-TOF), can take advantage of the high-resolution isolation of the precursor ion or the higher kinetic energy available for CID experiments.

5 MULTIPLE MASS SPECTROMETRY DETECTION

A sequence of mass spectral detection in a chain of fragmentation events originating from an analyte ion is called MS^n ($n = 1, 2, 3, \ldots$), in order to highlight the number of stages of mass analysis involved in the process (Figure 9). MS^n is a very general term and does not define any particular instrument configuration. Generally, any process leading to the detection of fragment ions originating outside the ion source can be included in this category. The simplest form of MS^n detection is a sequence of two mass spectral stages (MS/MS). In this mode, the first stage of mass analysis (MS_1) is used to isolate a selected ion (*precursor ion*) into a collision region. The precursor ion is

Figure 9 Conceptual representation of the technique of MS/MS. Ions with m/z 129 are selected by the first mass spectrometer; these ions are directed into a collision chamber and the decomposition products are analyzed by the second mass spectrometer to produce the product-ion spectrum of m/z 129. (Reproduced by permission from J. Throck Watson, *Introduction to Mass Spectrometry*, 3rd edition, Lippincott-Raven, New York, 1997, 110.)

Table 2 MS/MS capabilities of different analyzers

Analyzer	MS/MS configuration	Product ion mode	Precursor ion mode	Neutral loss	Utility	Resolution	Collision energy
Quadrupole	QQQ	✓	✓	✓	Sensitive in SRM	Low	Low
	EBQQ	✓	✓	✓	High precursor selectivity	Mixed	Both
	BEQQ	✓					
	Q-TOF	✓			Sensitive product ion spectra	High	Low
Trap	MS^n	✓			Versatile/affordable	Low	Low
TOF	Q-TOF	✓			Sensitive product ion spectra	Mixed	Low
Sector	EB	✓				Low	High
	BE	✓				Low	High
	BEB	✓			High performance	Mixed	High
	EBE	✓			High performance	Mixed	High

excited, usually by interaction with a collision gas (CID), leading to the formation of fragment ions (*product ions*). Product ions are eventually mass resolved in a second stage of mass analysis (MS_2). The energy involved in the decomposition process influences the extent and quality of fragmentation. As a rule of thumb a higher collision energy, like those achieved when MS_1 is a sector analyzer, leads to greater decomposition of any analyte precursor ion and, ultimately, more structural information. Both sensitivity and specificity are greatly enhanced in the course of an MS/MS experiment. The coupling of multiple stages of mass analysis provides further structural information. In the selected reaction monitoring (SRM) mode, a number of selected product ions are continuously monitored while a precursor ion is admitted in the collision region by means of the first mass analysis stage. This mode of operation, which resembles the selected ion monitoring (SIM) mode in EI, yields the highest specificity for target analytes. The sharp increase in the signal-to-noise ratio after any stage of MS/MS operation may lower the analyte detection limit.

As shown in Table 2, MS analyzers can be arranged in different configurations to realize an MS/MS detector. Most of them can be optically coupled in a twin or hybrid configuration. In an ion trap mass spectrometer, where mass analysis stages are separated in time instead of space, the MS/MS process does not require an optically linked chain of analyzers and can, in theory, be repeated indefinitely. Double-focusing magnetic instruments, designed to focus or select ions based on both energy and momentum, can be used alone in a variety of different low-resolution scan modes to allow products of dissociation in the field-free region to be detected (energy scans, linked scans). A sort of CID, where the precursor ions can be only chromatographically resolved, is also available with the ES interface by means of the curtain gas region. MS^n detection is of a crucial importance in HPLC/MS interfacing where most of the ionization techniques are 'soft' and considered insufficient for structural elucidation or analyte confirmation.

6 APPLICATION OF HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY IN PESTICIDE ANALYSIS

The heterogeneous group of chemicals known as pesticides can be found everywhere in the environment and their occurrence, even at low concentration, can be a serious threat to human health. In many cases capillary GC combined with the appropriate selective detectors or a mass spectrometer is employed. However, many pesticides currently in use are not amenable by GC owing to their polarity, thermolability and/or low volatility. In this case a separation in a liquid phase is more appropriate and HPLC/MS plays an important role.[18–21]

6.1 Thermospray Interface

Several classes of pesticides have been analyzed with TSP, demonstrating the extensive use of this technique in environmental analysis. Even though it has been replaced by newer interfaces, its importance in the field is worthy of a detailed description. Although TSP ionization is known to be 'soft', producing a poor fragmentation, several techniques can be used to enhance the performance of this interface, increasing structural elucidation capabilities. These include the control of the vaporizer temperature, the use of MS/MS and the possibility of working in positive ion (PI) and NI modes.

The performance of TSP ionization over a broad range of pesticides has been investigated in a number of interesting studies. Bellar and Budde developed a broad-spectrum method for the determination of nonvolatile target compounds in aqueous samples.[22] Several classes

of pesticides and herbicides, such as *N*-substituted amides, carbamates, sulfonylureas, triazines, phenylureas and others, were used to spike aqueous samples at 2–50 and 20–500 ppb levels for liquid–liquid and liquid–solid extraction. The TSP source was operated with the filament off, the discharge off and the repeller off and the detection was obtained in the PI mode. The LC mobile phase contained ammonium acetate alone or mixed with ammonium formate as ionizing reagent to perform volatile salt ionization (VSI) producing protonated molecular ions and other adduct $[M + H]^+$ and $[M + NH_4]^+$ ions. The detection limits obtained using liquid–liquid extraction ranged from 0.2 ppb for cynazine to 18 ppb for linuron, while those obtained with liquid–solid extraction were higher owing to the small size and limited capacity of the cartridges used. Combining the information obtained from the LC separation and those from MS, this approach allowed the satisfactory identification of the target analytes.

Volmer et al. conducted an interesting study on the dependence of the temperature and salt concentration on the ion abundance in TSP mass spectra of several pesticides under CID conditions.[23] In many instances, raising the vaporizer or the gas-phase temperature can promote further fragmentation. They demonstrated that, for some pesticide classes, fragmentation is mainly due to chemical reactions that occur in the gas or liquid phase rather than thermal decomposition. In another interesting paper, the same group demonstrated applicability of TSP in the determination of 128 polar pesticides, with a wide range of structures and polarities, in aqueous environmental samples with a detection limit of 100 ppt.[24] Sensitivity and selectivity were enhanced by postcolumn addition of aqueous buffer solution and the use of external ionization media. The mass spectrometer was operating in both PI and NI modes. In all experiments discharge-assisted buffer ionization (1000 V) was used to obtain a higher signal intensity, and LC/TSP/MS/MS experiments were carried out on a triple-stage quadrupole mass spectrometer, choosing $[M + H]^+$ and $[M + NH_4]^+$ ions as precursor ions. In combination with time-scheduled SIM, this method permits the detection of all pesticides at the 10–100 ppt level.

In a further developments, Volmer et al. examined a series of nitrogen- and phosphorus-containing pesticides, polar pesticides and sulfonylureas, employing off-line and on-line solid-phase extraction (SPE) and LC/TSP/MS with time scheduled SIM.[25–28] The precision, linearity and instrumental detection limits obtained allow the determination in full-scan mode of many analytes in the low nanograms per liter range, according to European Community Water Guidelines. In some cases, confirmation of the fragmentation pathways and further structural elucidation was obtained by comparison with APCI, ES, FAB, ^{252}Cf plasma desorption and CID spectra. Sulfonylurea herbicides and their degradation products in soil were also monitored in an early work by Shalaby et al.[29] PI full-scan spectra, with the post-column addition of a solution of ammonium acetate, were generated, allowing the simultaneous determination of the compounds of interest at the 0.02 ppm level.

In another effort to determine multiresidue pesticides and their metabolites at trace levels, SPE either on Empore C_{18} extraction discs or on a conventional column packed with PRP-1 copolymer followed by LC/TSP with time-scheduled SIM was performed.[30] The TSP/LC/MS system was operating in both PI and NI filament-on modes. Ammonium formate was added to the LC mobile phase. This approach allowed the detection of the selected compounds at concentrations of 0.02–0.4 $\mu g\,L^{-1}$ in the water samples. Calibration plots, constructed using spiked estuarine water samples, show good linearity for 16 of the 34 pesticides considered. The same approach was used to determine the persistence of temephos and its metabolites in rice crop field waters[31] and to determine chlorotriazine and its photolysis products in water.[32]

Sixteen carbamate pesticides were used in a very interesting comparison, under standardized experimental conditions, among three different TSP interfaces and ion sources to evidence possible differences ion formation and sensitivity of detection.[33] Twelve of the investigated compounds showed no significant differences in their mass spectra, especially at low temperatures. Thermally labile molecules such as asulam, thiodicarb and thiofanox showed significant differences in the mass spectra, mainly due to thermally assisted hydrolysis of the parent compounds in the vaporizer probe, not necessarily reflecting differences in the ion source geometry.

6.2 Electrospray Interface

ES is one of the most widely used interfaces in pesticide analysis thanks to its high sensitivity and versatility. However, the use of this interface is limited to ionic and polar compounds. The introduction of ES has broadened the horizon in the analysis of thermolabile and polar compounds. This interface requires very low LC flow rates ($<10\,\mu L\,min^{-1}$), meaning that the conventional LC column effluent must be split. Different solutions have been devised to overcome this inconvenience, one of them being the development of a pneumatically assisted ES interface (IS) that allows flow rates up to $2\,mL\,min^{-1}$. This interface is particularly suitable for thermally labile analytes because it allows the nebulization of the column effluent at low temperature. The application of an extraction cone voltage adds the possibility of collisionally induced fragmentation, to help structural elucidation. This feature is common

to all API techniques. An interesting paper compared the performance of LC/TSP/MS and LC/IS/MS for the simultaneous determination of 10 carbamate pesticides in spiked tap water and river water and in two different types of spiked sediments which exhibit large differences in polarity.[34] The use of the TSP interface for carbamate analysis had already been tested by the same group in a previous study in which they obtained satisfactory structural information, although sensitivity was not the point of force of this interface.[35] The use of LC/IS/MS leads to detection limits between 10 and 50 pg in the SIM mode, whereas in TSP the detection limits for the same compounds are typically between 0.5 and 5 ng. Also, the repeatability in the ion signal intensities is better with the IS system. Coextracted compounds do not interfere with the analytes of interest in sediments down to the 50 μg kg^{-1} level (Figure 10a and b).

LC/IS/MS has been used in the determination of polar and/or thermally labile organophosphorus pesticides in water samples prior to SPE.[36] This method permitted the identification also of some phthalates present as interferences, and the characterization of *cis*- and *trans*-mevinphos. The limits of detection were in the range 0.01–0.20 μg L^{-1} in the SIM mode.

Henion et al. reported the quantitative and qualitative determination of eight sulfonylurea herbicides in soil.[37] The experiments were carried out with LC/IS/MS/MS in the SRM mode, providing high specificity and high sensitivity down to 0.05 ppb.

In a more recent paper, a multiresidue method for the determination of six pesticides belonging to three major pesticides classes, carbamates, triazines and ureas, in water, using an in IS LC/MS interface with a narrow-bore system, is described.[38] In order to provide structural information, CID combined with mass analysis can be obtained by increasing the orifice voltage (OR) in front of the mass analyzer. In this work, two different ORs were used: a low voltage of 20 V gives peaks for the protonated molecule $[M + H]^+$ and the sodium adduct $[M + Na]^+$, and a high voltage of 60 V generates fragment ions from these precursor ions. This approach allows increased sensitivity without the need for a tandem analyzer instrument.

The spectra obtained at 60 V indicate that fragmentation had occurred by the expulsion from the protonated or cationated molecule of small, stable, neutral fragments. The results obtained are similar to those obtained with conventional MS/MS, the only drawback of this approach being that the chemical noise is not removed from the parent and fragment ion signals. This system allows detection limits lower than those required by the European

Figure 10 Filament-on NI TSP mass spectra of 0.5 μg of propoxur, with 50 : 50 acetonitrile–water, (a) without additives and (b) with 50 mM ammonium acetate as the carrier stream. Community Drinking Water Directive for the compounds analyzed.

Several other classes of pesticides were detected at ultratrace level using on-line liquid–solid and SPE LC/IS.[39,40] In the earlier study,[39] thermally labile and polar organophosphorus pesticides in water were detected at the $0.1\,\mu g\,L^{-1}$ level combining various SPE methods with IS. Detection limits were 100 times higher than those obtained with TSP, with no thermal degradation, which allows the detection of thermally labile compounds. Extraction of particularly delicate compounds was accomplished using off-line SPE followed by the MS analysis. In the later study,[40] several acidic pesticides such as benazolin, bentazone, 2,4-D, MCPA, MCPP, MCPB and 6- and 8-hydroxybentazone were detected in water samples at $0.01-0.03\,\mu g\,L^{-1}$ levels. With extraction voltages above 30 V it was possible to distinguish between the two isomeric products of bentazone, 6- and 8-hydroxybentazone. ES has been demonstrated to be a valid technique also in the determination of sulfonylurea herbicides in soil.[41] The sample was spiked at $6.0\,\mu g\,kg^{-1}$ with chlorsulfuron, metsulfuron-methyl, thifensulfuron-methyl and triasulfuron, cleaned up on a C_{18} cartridge after extraction, then analyzed using ES.

Di Corcia et al. have investigated in detail the possibility of determining several classes of pesticides in different matrices. Acidic and basic–neutral pesticides with a broad range of polarity were extracted from aqueous samples by means of graphitized carbon black (GCB) cartridges and analyzed by LC/IS.[42,43] The conventional column flow rate of $1\,mL\,min^{-1}$ was split and only $30-40\,\mu L\,min^{-1}$ were allowed into the ion source. The mass spectrometer was operating in the NI mode for the acidic compounds and a voltage of 20 V was applied to the skimmer cone, and in the PI mode with a voltage of 30 V for the basic–neutral pesticides. An ion-pair agent was added to the mobile phase in order to achieve the separation of the acidic pesticides. The ion signal was affected by the nature of the ion-pair and its counterion and also by the nature of the pesticide itself. The limits of sensitivity for the acidic pesticides were estimated to be $2-6\,ng\,L^{-1}$ in drinking water and $8-25\,ng\,L^{-1}$ in surface water, and for the basic–neutral pesticides they ranged from 1 to $9\,ng\,L^{-1}$ from total ion current (TIC) and from 0.06 to $1.5\,ng\,L^{-1}$ from extracted ion current profiles. With little difference in the procedures, Di Corcia et al. demonstrated that this approach could be applied to a wide range of pesticides. The same LC/ES system was used for the analysis of carbamate insecticides at the picograms per gram level in fruits and vegetables, operating in the PI mode with a skimmer cone voltage of 30 V and time-scheduled SIM.[16] Atrazine and its degradation products and sulfonylurea herbicides in water were also determined with the same instrumentation.[44,45]

6.3 Particle Beam Interface

The PB interface, in particular in its capillary-scale version,[17,46] is very competitive for the analysis of pesticides. Its major advantage relies on EI, which provides library-searchable, reproducible spectra of the analytes. Budde et al.[47] were among the first workers to evaluate the suitability of the PB as a major component of a general purpose, broad-spectrum analytical method for the determination of pollutants. The results were encouraging in terms of response linearity, reproducibility and detection limits for a wide selection of polar compounds. A comparison between PB and TSP in the analysis of phenoxy acid herbicides was reported in another paper.[48] TSP with NI detection showed better sensitivity, whereas the PB was more precise, particularly at the high concentration levels.

Phenoxy acid and ester herbicides were the target compounds in another method for their determination in soil and water.[49] The PB was used for the confirmation of UV detection results. Detection limits ranging between 12 and 80 ng, corresponding to 4.8–32 ppb in water and 20–133 ppb in soil, were obtained with this method. EI showed the molecular and the phenoxy (base) ions of the selected compounds for unambiguous identification.

The advantages offered by a capillary-scale interface, developed by Cappiello et al.,[50] were found particularly convenient for the analysis of a large number of basic–neutral and acidic pesticides. The improved sensitivity, especially in reversed-phase conditions, lowers the overall detection limits, allowing the low parts per billion level determination of the target analytes in water. However, the results relative to the acidic pesticides are still affected by thermal degradation and an apparent loss of chromatographic resolution when eluted from the column. The difference is noticeable when comparing the TIC profiles for basic–neutral and acidic pesticides.

A breakthrough in the analysis of these compounds is represented by the use of Teflon® as the target vaporization surface.[50] The validity of this approach is demonstrated by the analysis of 18 acidic pesticides with a Teflon®-modified ion source (Figure 11). The PI EI assay combines the advantages of a reduced mobile phase flow rate ($1\,\mu L\,min^{-1}$) with a more efficient solute vaporization surface. Under these conditions, the original chromatographic profile is reproduced more accurately, with no signs of analyte adsorption or thermal decomposition. Instrument detection limits are improved significantly (0.6–5 ng), exceeding the parts per billion limit for the determination of the pesticides in water.

Cappiello et al.[51] developed an HPLC method in which ion interaction chromatography was coupled with a capillary-scale PB, allowing the simultaneous detection of basic–neutral and acidic pesticides. This

Figure 11 Reconstructed ion chromatogram for the separation of a standard solution of 18 acidic pesticides: (1) 4-nitrophenol, (2) 2,4-dinitrophenol, (3) dicamba, (4) bentazone, (5) 2,4-D, (6) MCPA, (7) bromoxynil, (8) 3,5-dichlorobenzoic acid, (9) mecoprop, (10) dichlorprop, (11) 2,4,5-T, (12) warfarin, (13) 2,4-DB, (14) MCPB, (15) 2,4,5-TP, (16) dinoseb, (17) dinoterb and (18) pentachlorophenol. method was made possible by the ability of micro-PB to accept nonvolatile HPLC modifiers. Less than 0.1 ppb of several pesticides was detected in tap water using this procedure.

6.4 Atmospheric Pressure Chemical Ionization Interface

The applicability of APCI is similar to that offered by PB and has been demonstrated in several reports to be particularly suitable for pesticide analysis. The APCI interface was compared with other LC interfaces (TSP, IS, PB) in a study on the determination of *N*-methylcarbamates in pepper extracts.[52] TSP, working in the PI filament-on, mode provided good sensitivity, although some fluctuation of the ion signal perturbed the analyses. Further fragmentation could be induced for enhanced confirmatory capabilities. The PB interface used in this work was a conventional one and was mounted on the same mass spectrometer as utilized for TSP. In this configuration, the PB performance was not satisfactory, mainly because the transport of the analytes into the ion source was inefficient. The performance of IS was comparable to that of TSP, providing mainly protonated molecules, although more information can be obtained by varying the cone voltage. CID will allow further structure elucidation. APCI with a heated nebulizer permits both protonated molecules and fragment ions. API techniques, besides their ease of use, are complementary and readily interchangeable, allowing a wide range of compounds with different chemical properties to be analyzed (Figure 12a–g).

Figure 12 Background-subtracted flow injection analysis (FIA) spectra of methomyl obtained by IS/MS (250 ng) at OR (a) 50 V and (b) 70 V, (c) IS/MS/MS (250 ng), (d) APCI/MS (50 ng), (e) PB/CI (2 μg), (f) PB/EI (2 μg) and (g) TS/MS (250 ng). North, 'An Evaluation of Atmospheric Pressure Ionization Techniques for the Analysis of *N*-Methylcarbamate Pesticides by Liquid Chromatography Mass Spectrometry', *J. Am. Soc. Mass Spectrom.*, **3**, 378 (1992). Copyright 1992 by American Society for Mass Spectrometry.)

Ten different pesticides were determined in extracts of strawberries and plums. In order to select the most suitable LC/MS technique, an initial comparison between APCI and ES was made.[53] Spectra of the selected compounds were acquired using APCI and ES in both PI and NI modes, obtaining similar spectra, although for most compounds with ES the most significant ion was the sodium adduct ion. Limits of detection were comparable for most compounds with the two techniques, but APCI was more sensitive for aldicarb and its metabolites. For this reason and for greater flexibility with LC flow rates, APCI was the interface chosen. This method allowed detection limits as low as $0.02\,mg\,kg^{-1}$ to be achieved for most compounds, meeting Codex Alimentarius Commission requirements.

APCI/MS (APCI/MS/MS) coupled with single, short LC columns was successfully used for the determination of several pesticides and herbicides in tap and river water.[54,55] The short column allowed fast separation of the analytes, increasing sample throughput. The protonated molecules generated by the APCI interface were subjected to CID for structure elucidation and for the confirmation of target and unknown compounds. This instrumentation has been used to obtain CID spectral data in the PI mode with the purpose of building a spectral library. The same approach was used to analyze 17 different pesticides belonging to six different classes in aqueous samples. A comparison between APCI and IS was also performed. The two interfaces were operated under the same conditions, with no volatile acids added to the mobile phase. The two interfaces performed similarly in terms of limits of detection (0.1–50 ng in full-scan mode for 12 of the 17 pesticides. Two of the investigated compounds, fenchlorphos and bromophos-ethyl, were detected by neither interface. In order to facilitate interpretation of the spectra, an MS/MS library of the product-ion spectra of protonated molecules was produced. The recording of the spectra of 73 pesticides and their metabolites was accomplished first in the PI full-scan mode and then, with $[M + H]^+$ ions selected as precursor ions, in the MS/MS product-ion mode.

An automated on-line SPE/LC/APCI system was used for the analysis of organophosphorus pesticides in groundwater[56] and triazine and phenylurea herbicides in miscellaneous environmental matrices.[57]

ABBREVIATIONS AND ACRONYMS

AC	Alternating Current
ACG	Automatic Gain Controller
APCI	Atmospheric Pressure Chemical Ionization
API	Atmospheric Pressure Ionization
CI	Chemical Ionization
CID	Collision-induced Dissociation
DC	Direct Current
DLI	Direct Liquid Introduction
EI	Electron Ionization
ES	Electrospray
FAB	Fast Atom Bombardment
FIA	Flow Injection Analysis
GC	Gas Chromatography
GCB	Graphitized Carbon Black
GC/MS	Gas Chromatography/Mass Spectrometry
HPLC	High-performance Liquid Chromatography
HPLC/MS	High-performance Liquid Chromatography/Mass Spectrometry
IS	Ionspray
LC	Liquid Chromatography
LC/MS	Liquid Chromatography/Mass Spectrometry
MAGIC	Monodisperse Aerosol Generator
MS	Mass Spectrometry
MS/MS	Mass Spectrometry/Mass Spectrometry
NI	Negative Ion
OR	Orifice Voltage
PB	Particle Beam
PI	Positive Ion
RF	Radiofrequency
SIM	Selected Ion Monitoring
SPE	Solid-phase Extraction
SRM	Selected Reaction Monitoring
TIC	Total Ion Current
TOF	Time-of-flight
TSP	Thermospray
UV	Ultraviolet
UV/VIS	Ultraviolet/Visible
VSI	Volatile Salt Ionization

Immunochemical assays (immunoassays, IAs) are biochemical assays which work according to the law of mass action. They are based on the recognition of an antigen (Ag) or a hapten by antibodies (Abs). Abs are serum glycoproteins of the immunoglobulin (Ig) class and are produced by the vertebrate immune system against foreign material of high molecular mass. The result of the binding reaction between the Ab and an analyte is usually made visible by means of enzymatic, chemiluminescent, fluorescent or radioactive markers. According to the label used IAs can be classified into enzyme immunoassays (EIAs), radioimmunoassays (RIAs), fluorescence immunoassays (FIAs) or chemiluminescent immunoassays (CLIAs). The measuring range of most IAs for pesticides is in the parts per trillion to lower parts per billion range. A lot of samples can be analyzed within a short time, while only low sample volumes are necessary. In many cases (water, some liquid food samples) no extraction step and no cleanup are necessary. Not all assays are completely specific to one single compound. Cross-reactivities of the Abs with haptens similar to the analyte can be observed. In some cases, matrix effects may occur, especially with soil or colored food extracts. Therefore, validation of the assays for the matrix of interest should be carried out. As IAs are usually targeted at a single analyte or a group of analytes, multianalyte approaches using Ab arrays or a combination of immunochemical techniques with liquid chromatography (LC) are pursued.

1 INTRODUCTION

Interest in immunochemical assays for the determination of pesticides has been steadily increasing. IAs are now commonly applied for the analysis of contaminants in water, soil, food and body fluids.[1–9] The first immunological experiments had already been carried out as early as the late eighteenth century when Edward Jenner, an English physician, used cowpox to prevent infection with smallpox. Based on these studies Louis Pasteur developed the use of attenuated strains of microorganisms for successful vaccinations. Emile Roux and Alexandre Yersin then found that immunity is caused by soluble compounds of microorganisms, which they called toxins. These toxins induce specific compounds in the immunized animal, which were named ''antitoxins'' by Emil von Behring and Shibasaburo Kitasato (1890) and are now called Abs. The Ab ''generating'' compounds are known as Ags.

Around the turn of the century it was shown that Abs are not only produced against microorganisms and their toxins, but also by other substances such as milk, protein or plant-derived toxins. Paul Ehrlich was the first to carry out quantitative studies on Ag–Ab interactions. The great interest in this field led to the first book on immunochemistry, published by Svante Arrhenius in 1907.[10] Karl Landsteiner also belongs to the pioneers in immunochemistry. He systematically used small artificial molecules, which he called haptens, coupled to a carrier molecule for immunization. In 1923 Heidelberger and co-workers found polysaccharides to be antigenic as well.

Studies by Rodney Porter (1959) and Gerald Edelman (1961) have provided the chemical structure of the Ab molecule. The enormous variety of Abs was explained by Frank McFarlane Burnet in 1957, based on a hypothesis of Niels Jerne dating from 1955, the now widely accepted clonal-selection theory. It describes each Ab-producing

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

cell as carrying on its surface only one type of Ab as a receptor. The binding of a respective Ag to this receptor leads to a clonal expansion of this cell and to the maturation of Ab-producing cells.

Immunochemical methods have their origin in the medical field. The first IA, a RIA for the quantification of insulin in serum, was described by Yalow and Berson.[11] Later, radiolabels were replaced by enzymes in EIAs by Engvall and Perlmann[12] and Van Weeman and Schuurs.[13] Since then radiolabels have obtained broad application in medical diagnostics and environmental analysis.

IAs belong to the most common methodology in the field of immunoanalysis. Even though Abs are (still) produced by a biological process, IAs are nevertheless chemical analytical procedures. The basic principle applying to all immunoreactions is based upon the law of mass action. In the equilibrium reaction between a free Ag or a hapten, such as a pesticide, and the Ab forming the hapten–Ab complex HAb (=bound hapten), represented by Equation (1),

$$H + Ab = HAb \quad (1)$$

the affinity constant K determines the concentration ratio between the bound hapten and the free reaction partners, Equation (2):

$$K = \frac{[HAb]}{[H][Ab]} mol^{-1} \quad (2)$$

A low detection limit (DL) in an IA therefore requires a high affinity of the Ab toward the analyte, which is expressed by a high affinity constant. For further details refer to Hock et al.[14]

IAs are based upon the measurement of Ab binding-site occupancy by the analyte (Figure 1). This reflects the analyte concentration in the sample. Since the binding reaction does not produce a signal which can be detected by simple means, various markers, e.g. radioactivity, enzymes, or fluorescence, are employed for the detection of the immunoreaction (see section 3.2). However, more sophisticated techniques like some immunosensing methods do not rely on a label (see section 6).

Figure 1 Principle of the competitive IA. In the first format with immobilized Ab (a) the plates are coated with Ab. Analyte and enzyme-labeled analyte compete for the Ab binding sites. In the second format a hapten–protein conjugate is immobilized in the solid phase (b). This protein conjugate and the free analyte compete for the binding sites of the Ab in solution. 2 ANTIBODIES

2.1 Antibody Structure

Immunochemical analysis is based upon the specific reaction between an Ab and its corresponding Ag or hapten. Abs are part of the vertebrate defense system (for more details refer to immunology textbooks, for example Golub[15] and Roitt[16]). They are serum glycoproteins of the Ig class produced by the immune system against foreign material such as pathogens or xenobiotics, and bind the target substance with high selectivity and affinity. Although there are five distinct classes of Ab in most higher mammals (IgA, IgD, IgE, IgG, IgM) IgG makes up approximately 80% of the total Ig in human serum. Most IAs rely upon IgG as the major Ig.

The basic structure of an Ab molecule is shown in Figure 2. It consists of two identical heavy (H) chains and two identical light (L) chains stabilized and linked by inter- and intrachain disulfide bonds. The H- and L-chains are organized into variable and constant regions. The Ag binding site (combining site) is formed by the association of parts of the variable regions of the H- and L-chains, located at the amino terminal end. The variable regions of both chains are organized into three

Figure 2 Structure of IgG Abs and their fragments (modified after Hock et al.[17]). scFv is the recombinant antibody fragment, a single chain fragment containing only the variable region, FR is the frame region, V_L is the variable region of light chain, V_H is the variable region of heavy chain, C_L is the constant region on the light chain, CH_1, CH_2, CH_3 is a constant region on the heavy chain.

hypervariable or complementarity determining regions (CDRs) separated by four framework regions. The greatest amino acid sequence variation occurs within the CDRs whereas the framework regions are more conserved. It is assumed that the association of the CDR regions forms the combining site. The lower part of the molecule, the Fc (antibody fragment containing the crystallizable fragment) is responsible for some important biological effector functions such as complement fixation and is not necessary for Ag or hapten binding. It contains the last heavy chain domains. The whole of the Ig molecule or Ab fragments, $F(ab)_2$ and Fab (antibody fragments containing the antigen binding site(s)) can be used in IAs.

A substance that after injection into the body of a vertebrate induces a specific Ab synthesis, is called an Ag. Ags are principally macromolecules, for instance proteins, polysaccharides or nucleic acids. Synthetic polymers also belong to the antigens, i.e. they can be used as, or act as, Ags. Small molecules (haptens) such as pesticides have to be coupled to a macromolecular carrier to elicit an Ab response (see section 2.3). The ability of an Ab molecule to bind an Ag or a hapten specifically is controlled by structural and chemical interactions between the ligand and the Ab at the combining site. The Ag–Ab interaction is reversible and does not involve formation of covalent bonds.[16] The binding is a result of a variety of interactions such as hydrophobic, ionic, H-bonding, π-π electron interaction, and van der Waals forces. The binding energy (relative affinity of the Ab) increases with the number of specific chemical interactions between the analyte and the amino acid residues in the Ab combining site. Therefore, the selectivity and sensitivity of an IA is controlled by the nature of the Ag–Ab binding process.

2.2 Antibody Production

Ab production is conveniently carried out in warm blooded animals, e.g. rabbits, sheep, mice or chickens.[17] Polyclonal antibodies (pAbs) are obtained from the serum and comprise a mixture of different Ab populations. Monoclonal antibodies (mAbs) consist of a single monospecific Ab population. These Abs are produced in cell culture by a single hybridoma cell derived from the fusion of B-lymphocytes with myeloma cells.[18] The hybridoma cells can then be propagated almost indefinitely in culture and will continue to produce the Ab of the lymphocyte parent. Since an individual lymphocyte produces only a single Ab type, all of the Ab molecules produced by a hybridoma cell line derived from a single hybrid cell are identical and have the same binding properties. Therefore, the hybridoma technology guarantees the unlimited production of mAbs with constant characteristics.[19] Owing to the great effort involved in mAb production many IAs still employ pAb. A third possibility for creating Abs has emerged, recombinant antibody (rAb) techniques. Here, Ig genes can be cloned, introduced and expressed in inexpensive and relatively simple host systems.[20,21] Although several nonmammalian host systems (yeast, plant and insect cells) have been used to produce rAbs, the most common vehicle is *Escherichia coli.*[22,23] The main properties of pAbs, mAbs and rAbs are listed in Table 1.

2.3 Immunogens

Most pesticides are of low molecular mass and therefore are not ordinarily antigenic. They have to be coupled to a carrier molecule, usually a protein, in order to induce an Ab response in the vertebrate immune system.[14] The site of coupling to the carrier, the coupling procedure as well as the number of haptens bound to one carrier molecule can be of major importance for the sensitivity and the selectivity of the resulting Ab (for reviews refer to Erlanger,[24,25] Goodrow et al.[26] and Szurdoki et al.[27]).

The protein carriers used in various laboratories include globulin fractions, serum albumins of different species, hemocyanin, ovalbumin, thyroglobulin, and fibrinogen. Also nonproteinaceous carriers have been used such as liposomes or dextran.[28,29] Keyhole limpet hemocyanin (KLH), a protein from mollusks, is often viewed

Table 1 Properties of polyclonal, monoclonal and recombinant Abs

Properties	pAb (Ab from serum)	mAb (Ab from hybridoma cells)	rAb (Ab produced by gene technology)
Supply	Limited and variable	Unlimited production possible	Unlimited production possible, immunization not mandatory
Uniformity	Changing properties with different sera and bleedings	Constant properties of a mAb	Constant properties of a rAb, can be changed by genetic manipulations
Affinity	Mixture of Ab with different affinities, affinity often higher with pAb	Uniformly high or low, can be selected by testing	Uniformly high or low, can be selected by testing and can be modified
Cross-reactivity	Results from different selectivities and low affinity interactions	Different, dependent upon the individual Ab	Different, dependent upon the individual Ab, can be modified
Classes and subclasses	Typical spectrum	One defined isotype	Different, depending on molecular design
Demands on Ag	High purity required for specific antisera	Impure Ags or mixture of Ags can be used for immunization, pure Ags necessary for screening	Impure Ags or mixture of Ags can be used for immunization, pure Ags necessary for screening, immunization not mandatory
Costs	Low	High	Once established, low

as a superior carrier because it is foreign to the vertebrate immune system.[30]

Another important issue concerns the optimal number of haptens bound to the carrier protein (i.e. optimal epitope density). Highly substituted carriers usually lead to the best results. For bovine serum albumin (BSA) molar ratios of 10 : 1 to 20 : 1 (hapten : carrier) are desirable; for larger molecules such as hemocyanin, ratios of 800 : 1 to 1000 : 1 should be obtained.[17] However, very high ratios may reduce immunogenicity because of either the changes in tertiary structure of the protein caused by masking of the essential free amino groups or the removal of critical determinant sites on the carrier by haptenic blocking.

For the production of pAbs the purity of the hapten used to prepare an immunoconjugate should be as high as possible. After synthesis of haptenic substances, closely related substances may be present in small quantities, leading to the production of nonspecific Abs and, consequently, to unwanted cross-reactivities of the antisera. This is not a problem with mAb, because a single cell line producing only one kind of Ab with the desired properties can be selected.

Another important consideration is the point of attachment on the hapten. Ab specificity is directed primarily at the part of the hapten molecule farthest away from the functional group that is linked to the protein carrier.[25] Even better specificity can be obtained with conjugates in which the hapten is coupled to the carrier via a spacer, thereby giving much better exposure of the hapten on the surface of the carrier. The spacer should be attached as far as possible from the unique determinant structures.[26] Usually C_3–C_6 spacers are used; if the spacer is too long, it may bend back to the carrier and the hapten will not be properly exposed. Strategies for IA hapten design for the triazine, arylurea and chloroacetanilide herbicides have been summarized by Goodrow et al.[26]

The functional groups of the hapten govern the selection of the method to be used to conjugate the hapten to the functional groups of the carrier. The functional groups of the protein carrier available for attachment of the haptens are the carboxyl group of the C terminal and of the aspartic and glutamic acid residues, the amino group of the N terminal and the lysine residues, the imidazol and phenolic functions of the histidine and tyrosine residues, respectively, and the sulfhydryl group of cysteine residues. General procedures for the preparation of conjugates can be found in Erlanger.[24,25]

After coupling, characterization of the conjugates can be carried out (see Erlanger[25]). Generally, the haptenic groups have an absorbance spectrum that can be differentiated from the protein carrier. Elemental analysis for the chlorine content can be carried out for some triazine conjugates. A more direct procedure is the incorporation of some radioactive hapten in the conjugation procedure. Another approach is quantitating the change in free amino groups as a result of conjugation. A recently applied technique is the determination of hapten density by matrix-assisted ultraviolet laser desorption/ionization mass spectrometry (MALDIMS)[31] and electrospray ionization mass spectrometry (ESIMS).[3] Application of energy-minimized molecular modeling methods to hapten design will help to choose the best derivatives and conjugation methods for successful Ab production.[32]

3 IMMUNOASSAY TYPES

3.1 Assay Formats

For low-molecular-mass analytes (haptens) such as pesticides in solution, competitive tests have to be employed, using limiting Ab concentrations. The tests can be performed as homogeneous assays without separation of the reactants,[33] but more common are heterogeneous tests where unreacted reagents are removed before evaluation. Two different formats are available, (1) with immobilized Ab (Figure 1a) and (2) with immobilized coating conjugate (Figure 1b). In variant (1) analyte and a labeled analyte (tracer) compete for the free Ab binding sites. After removal of unbound reactants the bound tracer yields a signal that is inversely proportional to the analyte concentration. The variant (2) employs an immobilized hapten-carrier conjugate on the solid phase to which analyte and Ab are added. The Ab binds to the free analyte or to the immobilized hapten according to the concentration of the reactants. If a labeled Ab is used, the amount of Ab bound to the solid phase can be directly determined after a washing step. Alternatively, a secondary labeled Ab may be used to detect the Ab which has bound to the solid phase. The signal is inversely proportional to the amount of free analyte in the sample. Very sensitive competitive IAs have been developed with DLs between 1 and 50 ng L^{-1}, for example for the triazines and urea herbicides.[34–36]

An example for a homogeneous assay system is the polarization fluoroimmunoassay (PFIA). PFIA measures the increased polarization of fluorescence when a fluorophore-labeled hapten (tracer) is bound by a specific Ab, and the decreased signal when free analyte competes with the tracer for binding.[37] While these assays are easy to carry out and very suitable for automation, they usually show a lower sensitivity than EIAs, e.g. for simazine a DL of 5 μg L^{-1} was observed.[37]

Noncompetitive assays can only be applied for high-molecular-mass analytes with more than one antigenic determinant (i.e. Ag) or low-molecular-mass analytes (haptens) bound to a solid phase, exposing the antigenic determinant. They work with an Ab excess. Noncompetitive IAs have been employed for the detection of soil-bound pesticides.[38,39] In this case the soil particles, to which the pesticide residues have bound, form the solid phase, and the residues can be detected by a labeled Ab specific to the analyte.

3.2 Labels

Depending on the label, IAs are classified in different groups. Radioisotopes are used in RIAs, enzymes in enzyme-linked immunosorbent assays (ELISAs) or EIAs, fluorophores in FIAs or PFIAs and chemiluminescent compounds in CLIAs. Additional types of IA exist, but are not very common in pesticide analysis. A more detailed description of these IAs can be found in Gosling.[40]

EIAs are most commonly used in pesticide analysis as they avoid the necessity of working with radioactive material and low DLs can be reached. Simple and cheap photometers which give an extremely rapid measurement capability and long-lasting stability of the colored product after the reaction has stopped make EIA superior to fluorimetry or luminometry, even though with these methods lower DLs may be reached.[33] Enzymes commonly used as labels in heterogeneous EIA are listed in Table 2.

Table 2 Enzyme systems commonly used for EIAs

Enzyme	Source	Molecular weight	pH optimum	Colorimetric substrates	Fluorometric substrates	Luminometric substrates
Alkaline phosphatase	Calf intestine	100 000	9–10	*p*-Nitrophenyl-phosphate	4-Methylumbelliferyl-phosphate	Adamantyl-1,2-dioxyethane Phenylphosphate-substituted dioxyethane
β-Galactosidase	*Escherichia coli*	540 000	6–8	*o*-Nitrophenyl-β-D-galactopyranoside Chlorophenolic red-β-D-galactopyranoside	4-Methylumbelliferyl-β-D-galactopyranoside	–
Peroxidase	Horseradish	40 000	5–7	2,2′-Azino-di(3-ethyl-benzthiazoline sulfonic acid-6) (ABTS)/H_2O_2 3,3′-5,5′-Tetramethyl-benzidine (TMB)/H_2O_2 *o*-Phenylendiamine (OPD)/H_2O_2	*p*-Hydroxyphenyl-acetic acid *p*-Hydroxyphenyl-propionic acid	Luminol

Table 3 Solid phases used for EIAs

Material	Form	Binding	Capacity
Polystyrene	Microtiter plates, tubes, pins, beads	Noncovalent	250–500 ng cm^2
Polyethylene	Tubes	Noncovalent	ca. 300 ng cm^{-2}
Polypropylene	Microtiter plates	Noncovalent	ca. 300 ng cm^{-2}
Polyvinylchloride and similar	Microtiter plates, membranes	Noncovalent	ca. 300 ng cm^{-2} (plates)
Polycarbonate	Beads, membranes	Noncovalent	ca. 300 ng cm^{-2} (beads)
Nitrocellulose	Microtiter plates, membranes	Noncovalent	ca. 100 µg cm^{-2}
Protein A coated	Microtiter plates, beads	Noncovalent	20 mg mL^{-1} (for Ab only)
Activated polymer, with amino or carboxyl groups	Microtiter plates, beads	Covalent, using bifunctional reagents	2×10^{13}–1×10^{14} reactive sites/cm^2
Magnetic	Beads	Depends on the surface of the beads	Varies

The following requirements are necessary for the use of an enzyme as a marker:

(1) high specific activity (turnover number) of free enzyme and after labeling,
(2) availability of soluble, purified enzyme at low cost and reproducible quality,
(3) high stability in free and conjugated form under storage and assay conditions,
(4) presence of reactive groups for covalent linkage to hapten,
(5) simple and gentle conjugation methods,
(6) inexpensive and stable nontoxic substrates with formation of stable chromogenic, fluorogenic and/or chemiluminogenic products.

3.3 Solid Phases

IAs are mainly carried out in 96-well polystyrene, polyethylene, polypropylene or polyvinyl microtiter plates, owing to the easy separation of the reactants in a washing step, but polystyrene tubes, beads or pins are also available (Table 3). The plastic plates are of comparatively low binding capacity and low surface area to volume ratio. High-binding supports include agarose and cellulose. Particulate solid phases are very efficient, because they become scattered throughout the reaction mixture and have a much higher surface area to volume ratio.[41] For example, many chemically different beads are available (e.g. polystyrene, latex, polycarbonate and copolymer beads). Immunological reagents are bound to the beads in a similar manner as they are to microtiter plates. Separation of bound and free reagents occurs by washing and centrifuging. IAs using magnetic beads employ a magnet for the separation step.[42] Abs and Ags may be immobilized to some solid phases via covalent binding. Those solid supports contain amino or carboxy groups on a modified surface through which the immunoreagents can be bound by water-soluble carbodiimides or bifunctional reagents such as glutaraldehyde.

Other solid-phase supports for IAs are membranes. They can be used for dip sticks, which are incubated for a short time in the solution[36] or for dot blots and immunofiltration tests. Here the reactants are filtered through the membrane.[43,44] The test principle is the same as for the microtiter plate tests but the reaction time is much shorter owing to the high surface area of the membrane and the short distance between reaction partners. Application of remission measurements yields a proportional relationship between analyte and remitted light. By using a pocket reflectometer, this set-up is ideally suited for field-monitoring purposes.[45,46]

4 PROPERTIES OF COMPETITIVE IMMUNOASSAYS

4.1 Dose–Response Curve

In IAs the signal produced is inversely correlated to the analyte concentration in the sample (Figure 3a). The typical dose–response curve is of sigmoidal shape when the signal is plotted versus the logarithm of the analyte concentration. A linear range is obtained around the middle of the test (IC_{50}, middle of assay, concentration of analyte that causes 50% inhibition), which should be used for determinations. Within this working range, the change in absorbance is linearly correlated to the analyte concentration. The linear part of the curve is confined by the upper and lower limits of quantification. These are the cut-off values above or below which quantitative results can be obtained with a stated relative precision, or specified degree of confidence in real samples.[47] The experimental errors increase toward these limits. Consequently, the most

Figure 3 EIA for the determination of atrazine using pAb. (a) Absorption curve (means of three determinations ± standard deviations), (b) B/B_0 curve, and (c) logit/log transformation by the two-parameter fit.

precise measurements are obtained in the region close to the middle of the test.

The DL (or least detectable dose) is the smallest concentration of the analyte that produces a signal which can be significantly distinguished from zero for a given sample matrix with a stated degree of confidence. Very often a dose is selected which inhibits 10–20% of enzyme tracer from binding with the Ab or the dose calculated after subtraction of two or three times the standard deviation from the mean measurements of the zero dose signal.[3]

Linearization of the calibration curve is useful for many purposes, for instance, for the direct comparison of curves if matrix effects are evaluated. Absorbance curves can be normalized by converting the absorptions to $\%B/B_0$ values. These can be expressed as the ratio of bound tracer in the presence of hapten to bound tracer in the absence of hapten and lies between 100% ($=A_0$, the upper asymptote of the curve) and 0% ($= A_{\text{Excess}}$, the lower asymptote) (Figure 3b). They are calculated by Equation (3):

$$\frac{\%B}{B_0} = \frac{A - A_{\text{Excess}}}{A_0 - A_{\text{Excess}}} \times 100 \tag{3}$$

Linearization can be obtained by various mathematical transformations.[47] Usually, IAs are evaluated with commercial IA programs, often based on logistic models (cf. Rodgers[48] and Dudley et al.[49]), e.g. four-parameter models or the more simple logit-log transformation (two-parameter model, Figure 3c) which can also be carried out with a calculator (s), Equation (4):

$$\text{logit}\,\frac{\%B}{B_0} = \ln\frac{\%B/B_0}{100 - \%B/B_0} \tag{4}$$

4.2 Quality Control

Precision and accuracy of IA are important properties which deserve special attention. The quality and stability of the employed material (microtiter plates, pipettes) and reagents (e.g. Abs, enzyme tracer or buffers), play a crucial role.[50] The long-term stability of reagents has to be ensured, e.g. by freeze-drying of Abs and, if necessary, addition of stabilizing components to the test reagents such as the enzyme tracer.[51]

In spite of the simple handling of the assays, expert knowledge is required, especially to recognize and remove incident errors. Therefore, IAs should be performed by trained personnel. The development of simple and rapid assays, such as dip-stick assays or immunofiltration tests reduces the requirement for trained users, but one has still to be aware of potential problems such as interferences from the sample matrix.

The precision of an IA is defined as the extent to which replicate analyses of a sample agree with each other. The reproducibility is the ability to yield the same results within analyses, between analyses, and between operators. The investigation of the variability of an IA gives valuable information about the consistency of the test. Coefficients of variation (CV) of IA measurements are usually between 10 and 20% for an optimized assay,[52,53] although more precise results can be obtained.[54,55] Same-day and day-to-day CV of samples have been determined in different matrices.[53,56] Interlaboratory tests of the same IA as that carried out by Hock and the IA Study Group[57] and Hayes et al.[58] for the investigation of triazines help to evaluate the general applicability of a test. However, several conditions like exact description of the assay including calibration curves, DLs, cross-reactivities, a working range close to the middle of the

test, enough parallel measurements, etc. must be met (see also AOAC (Association of Official Analytical Chemists) criteria). Meanwhile, standardized procedures for IAs in water are adopted by AOAC International and have been established in Germany as a prenorm.[50,58]

A validation of the results obtained by IA should be carried out. To a limited extent this can be done by IA itself. Dilution of the samples as well as spiking of the authentic sample with known amounts of the contaminant can be used to check whether the matrix interferes with the IA.[59] However, spiked samples do not completely mimic real unknown samples. They do not contain potential metabolites of the contaminant nor residues from other compounds which may be present in real samples. Furthermore, spiked samples cannot be a model for aged residues which are more difficult to extract and detect because, for example, they may have bound to soil constituents. Therefore, an IA should also be validated by a different established method like high-performance liquid chromatography (HPLC), gas chromatography (GC) or GC/MS (gas chromatography/mass spectrometry). Many groups have used this approach and have usually obtained correlation coefficients of >0.9.[60–63] Often a slight overestimation of the IA in comparison with HPLC or GC is observed owing to cross-reactivities of the Ab or matrix effects.

4.3 Cross-reactivity

Depending on the conjugate used for immunization and the class of chemicals under investigation, cross-reactivities of the Ab with haptens similar to the analyte are frequently observed (see e.g. Hock[14] and Harrison et al.[64]). Therefore, it should be checked which compounds cross-react to what degree with the Ab. This is usually done by comparing the standard curves of the analyte under investigation with similar haptens, using analyte concentrations at 50% of the inhibition curve as the reference. However, cross-reactivity with a certain analyte is not the same over the whole range of a standard curve. Often higher cross-reactivities can be observed at low concentrations of the cross-reacting analyte.[3] Therefore, it has been recommended that cross-reactivities be measured at different concentrations over the range where the assay is suitable.[65]

If an Ab is selective for a single compound, it is regarded as monospecific[66] (Figure 4). An Ab that recognizes several compounds to the same extent (e.g. a group of s-triazines), can be used for the screening of a class of herbicides[67] (group-specific Ab, Figure 4). If cross-reacting compounds are not expected in the samples, because the compounds are not licensed (e.g. propazine in most European countries), a group-specific Ab can also be used for quantitative measurements of one compound.[68]

Figure 4 Selective, intermediate and group specific Abs. This example uses Abs which have been produced against hapten 1. Substances 2–5 are assumed to be cross-reacting haptens (modified after Hock et al.[14]).

Strong cross-reactivities of an Ab to unexpected metabolites, for example, can produce false positive values. An Ab for alachlor was found to react very strongly to the sulfonic acid metabolite using an alachlor screening kit.[69] This problem could be solved, however, by using solid-phase extraction (SPE) prior to IA and sequential elution of the two compounds with different organic solvents.

4.4 Sample Preparation and Matrix Effects

Samples can contain compounds in addition to the target analyte, which may interfere with the test. Several groups investigated the influence of ions on EIAs.[70–72] Ruppert et al.[70] observed an inhibition by several anions like azide, which inhibits the peroxidase by binding to the heme group of the enzyme. Most cations did not have an effect except for Ca^{2+}, which leads to an activation of the peroxidase. No interference by different ions such as nitrate, copper, magnesium etc. up to a concentration of 250 ppm was detected in an EIA for pentachlorphenol in water.[71] While ions may inhibit the enzyme used as a label or lead to precipitates by reacting with the buffer components, humic substances present in water or soil extracts may bind nonspecifically to the Ab and thereby interfere with the specific binding of the analyte.[73] These reactions may lead to false positive results. Water samples from forest stands or soil extracts particularly contain a high content of organic compounds such as humic acids (HAs).

Matrix effects in food samples frequently occur owing to colored extracts or to the content of lipids, proteins or polyphenols that may be coextracted during sample preparation.[74] As food samples usually have to be extracted prior to immunochemical analysis, the method of analyte extraction is of great importance. Analytes

that are water soluble and can be efficiently extracted in aqueous buffer will have the most direct extraction method and eliminate the need for organic solvents. However, many pesticides are not readily water soluble and must be extracted with an organic solvent.[5] For the extraction of pesticides from solid foods a variety of solvents have been tested, such as acetone, ether, petroleum ether, methanol, acetonitrile or hexane.[75] Direct analysis of extracts by IA requires the use of solvents that are miscible with water and (at low concentrations) are nondenaturing to proteins such as Ab. IAs are to a certain degree tolerant to a variety of solvents, but each system must be tested to determine which solvent can be accepted and to what extent (for example Hill et al.,[75] Nugent[76] and Schneider and Hammock[77]). Usually the extracts are further diluted with water prior to the EIA, but an EIA for parathion was developed, in which the analyte dissolved in hexane could be directly measured in the EIA without prior removal of the hexane. This was achieved by using Ab encapsulated in reverse micelles composed of Aerosol T with aqueous centers.[78] However, a 10^4-fold decrease in sensitivity was observed.

In some cases a cleanup step is introduced, in which the analyte of interested is separated from the matrix. This can be carried out by C_{18}-columns or immunoaffinity columns.[69,79,80] A very interesting approach is the application of supercritical fluid extraction (SFE) prior to immunoanalysis. These methods generally employ CO_2 or CO_2 containing various modifiers.[5,81]

Some problems with interfering ions can be solved by changing the buffer of the assay system so that no precipitates may be formed.[70] Addition of BSA to the plates prior to the addition of the standard and sample solutions[82] or to the enzyme tracer[73] greatly reduces the influence of humic and fulvic acids on the EIA. It may also be helpful to switch to a different batch of Abs or a different assay kit, as different Abs may show different sensitivities to interfering substances. The buffering capacity of the assay buffer should also be checked, as some water or food samples may show relatively low pH values. No effects, however, were observed between pH 3 and 10 by different investigators.[56,67,83]

5 APPLICATION TO ENVIRONMENTAL SAMPLES

IAs have been developed for many environmental contaminants during the 1990s. A list of several IAs described in the literature can be found in Table 4. Most of them have been developed in laboratories, showing the increasing importance of immunochemical methods in residue analysis. Not all of them are commercially available. Available commercial IAs have been listed in e.g. Dankwardt et al.,[2] Hennion and Barcelo,[3] Knopp,[8] but a lot of movement has been observed in environmental IA markets, leading to the disappearance of IA companies. At the moment IAs for environmental contaminants can be obtained for example from Strategic Diagnostics Inc. (Newark, DE, USA, sells former Ensys, Millipore and Ohmicron kits) and EnviroLogix (Westbrook, MA, USA).

5.1 Water

EIA have been used intensively for the determination of pesticides in surface and rainwater[56,60,69,211–217] and groundwater.[60,69,214,218,219] A substantial number of these studies were carried out for triazine herbicides.[56,60,211,212,214,216,218,219] This illustrates the widespread occurrence of these herbicides in the aquatic environment. Many groups have used commercial test kits, which allow the investigation of samples without time-consuming Ab production. Thurman et al.,[60] for example, used a Res-I-Mune kit (ImmunoSystems) for the investigation of triazines in surface and groundwater. The EIA was compared to GC/MS results obtained from samples that were extracted by SPE. Correlation coefficients between 0.91 and 0.95 were obtained after introducing cross-reactivity factors for each of the triazines in order to calculate a sum parameter for the GC. The majority of the samples contained only atrazine (up to $3\,\mu g\,L^{-1}$). Therefore, the EIA results corresponded well with the atrazine concentrations obtained by GC/MS.

Mouvet et al.[220] compared four commercially available test kits and one in-house developed assay for the determination of triazines in surface and groundwater. Operational characteristics, cross-reactivity, sensitivity, CV and agreement with GC/LC (gas chromatography/liquid chromatography) measurements were investigated. DLs were determined between 0.003 and $0.07\,\mu g\,L^{-1}$. Intra-assay CVs were below 7% for all tests, interassay CVs below 20%. Correlation studies between the EIA kits and GC/LC were carried out for samples from different water matrices. Depending on the water source, different levels of significance were observed with different tests. The best results were obtained for surface water, while not all kits showed a good agreement for lysimeter samples.

Apart from the triazines some other pesticides were investigated in water samples, also using commercial test kits. Alachlor was determined in ground and surface water using commercial tests.[213] SPE was carried out prior to EIA to remove interfering substances and to concentrate the analyte. Concentrations of up to $0.8\,\mu g\,L^{-1}$ were observed, and a comparison with GC/MS

Table 4 Pesticide IAs described in the literature

Pesticides	Test format	Ab	Range, DL, or middle of test (IC_{50})	Ref.
Herbicides				
Alachlor	EIA	p	0.2–8 µg L^{-1}	84
	EIA	p	0.1–10 µg L^{-1}	85

MCPB, 4-(4-chloro-2-methylphenoxy)butyric acid; 2,4,5-T, 2,4,5-trichlorophenoxyacetic acid; DDA, bis(*p*-chlorophenyl)acetic acid; DDT, 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane; 2,4-D, 2,4-dichlorophenoxyacetic acid; PCP, pentachlorophenol. NA, not available.

showed a correlation coefficient of 0.95 with a slight underestimation by EIA. The occurrence of carbaryl was determined by Marco et al.[221] in wellwater from Spain with their own assay and compared with a commercial test kit. Both IAs yielded a good agreement with conventional methods. Concentrations of 0.08–1.37 μg L^{-1} were observed. Two commercial test kits were used in the Netherlands to determine 2,4-D concentrations in the rivers Rhine and Meuse.[217] By diluting the kit standards with kit zero-buffer and calculating the DL on the basis of the error in the zero-standard, the DL as originally indicated by the manufacturer was significantly lowered. The water matrix substantially affected the recovery of 2,4-D with one assay kit, yielding unexpectedly low recoveries in demineralized and tap water. However, similar results were obtained by EIA and GC/MS for spiked samples from the river Rhine (with a slope of about 1 and $r = 0.99$). Routine samples were also analyzed

and yielded analyte concentrations mostly below the DL ($0.03–0.05\ \mu g\ L^{-1}$).

5.2 Soil

Many studies for pesticides in soil have been carried out for triazines.[38,73,222–227] Other analytes include carbofuran,[72] chlorpyrifos,[178] hexazinone,[119] metolachlor,[227] 4-nitrophenol,[184] PCP,[71] and triasulfuron.[157,228]

Usually, the pesticides are extracted from soil with organic solvents such as acetone, ethyl acetate or methanol. In some cases, for example in the investigation of the quite water-soluble atrazine, extraction with water was sufficient. In one study no difference was observed in EIA measurements after extraction of atrazine from corn fields with water or acetone.[225] Owing to the extraction with water it was very easy to apply the samples directly to the IA. However, in most cases the sensitivity of the assays is high enough to dilute organic solvent extracts sufficiently so that they do not interfere with the assay. The use of supercritical fluids for soil extraction is becoming increasingly popular. The low critical temperature (e.g. 31 °C for CO_2) means that low extraction temperatures can be used to recover thermally unstable solutes.[184,229] Wong et al.[184] compared SFE with solvent extraction using ethyl acetate for the investigation of parathion and 4-nitrophenol from soil. The extracts could be measured directly after SFE by IA or GC without solvent exchange. Similar concentrations were observed by both extraction methods.

The use of IA with magnetic particles has been described for the investigation of PCP, carbofuran, and triasulfuron in soil.[71,72,228] The dispersion of the covalently immobilized Ab on the surface of the magnetic beads results in a more even distribution in the sample and leads to a lower variability of measurements, which is usually higher in soil extracts than in water samples.

Immunochemical methods have also been applied to the detection of bound pesticide residues in soil. These are formed by binding of pesticides to the organic matter of the soil, mainly humic and fulvic acids, and cannot be analyzed using common extraction and assay methods. Hahn et al.[223] used Fab fragments labeled with a fluorescent dye to detect nonextractable residues of atrazine in soil from corn fields. The fluorescence signal obtained was related to the amount of bound atrazine in native soil samples determined by GC after supercritical methanol extraction. A noncompetitive sandwich IA for the analysis of bound residues based on HA–Ab and triazine Ab was developed by Ulrich et al.[38] HA was extracted from soil, bound to the plates by the HA–Ab and the nonextractable triazine residues were detected by a peroxidase-labeled Ab against triazines. Concentrations of bound atrazine were found in the region of 2 mg per kg soil in corn fields with a long history of atrazine application. A competitive EIA was used by Dankwardt et al.[225] for the investigation of bound residues. Free atrazine residues were removed from organic matter extracts by SPE and the extracts were then measured by EIA.

5.3 Food

A variety of pesticides has been determined in food samples by EIA. In many cases Abs against the target compound were developed in-house. Mainly pAbs were still used, but mAbs were applied for the determination of atrazine, benzimidazoles, thiabendazoles and carbaryl.[46,201,208,230]

Peel of apples, potatoes, oranges, grapefruits and bananas were investigated for thiabendazole residues employing an EIA with mAb.[231] Residues were extracted by soaking peel overnight in 80% methanol and filtering the decanted supernatants. Most of the thiabendazole was extracted within 1 h, but an extraction time of 16 h was chosen as uniformly high recoveries from all matrices were obtained. A 20-fold dilution eliminated significant matrix effects. The EIA had a DL of 0.1 ppm in peel samples, corresponding to 10–40 ppb in the whole fruit or tuber. Results obtained by EIA were compared with HPLC analyses. Although the EIA values were higher compared with the HPLC results, the two sets of data correlated well. The higher values by EIA were attributed to the loss of thiabendazole during sample work-up for HPLC and the high dilutions necessary for EIA.

Triadimefon was added to different food commodities such as apples, pears, pineapples and grapes. Fungicide residues were determined by EIA and GC after extraction with ethyl acetate or methanol.[209] Ethyl acetate was required to extract grapes for the EIA procedure, since methanol resulted in coextractives which gave too low values. Methanol, however, yielded good recoveries at 0.5 ppm and above for other commodities and is preferable to ethyl acetate because it avoids an evaporation step. Low recoveries were obtained at 0.1 ppm and were not improved using ethyl acetate. On the whole, recoveries obtained by EIA correlate well with those measured by GC. The middle of the test was observed at $2.4\ \mu g\ L^{-1}$.

A mAb-based EIA was applied to the determination of carbaryl in apple and grape juices.[230] The juices were used without any sample pretreatment and spiked with different carbaryl concentrations. The influence of matrix dilution was investigated using different dilutions of the samples. For proper analysis the samples should be diluted at least 1 : 5–1 : 10. With a dilution of 1 : 100 the most accurate and precise results were obtained.

Therefore 2–5 $\mu g\,L^{-1}$ are considered the lowest cabaryl concentrations in juices that can be reliably measured with the EIA. CVs ranged from 4 to 13%, with most of them below 8%.

A dip-stick IA using mAb immobilized on a membrane was used for the determination of atrazine in water and liquid food samples.[46] The measuring range was 0.3–10 $\mu g\,L^{-1}$ using reflectance detection. The total assay time was 25 min using precoated dip sticks. The atrazine concentrations could be determined directly in spiked water, milk and juice samples yielding satisfactory agreement with the spiking concentrations. The black tea samples, however, showed an overestimation due to the unspecific binding of the tannins to the membrane.

Paraquat was determined in milk, beef and potatoes using an EIA with pAb.[232] Potatoes were shredded with dry ice. The potato and the meat samples were extracted with HCl after spiking the samples. The acid extracts were evaporated to dryness and reconstituted for the EIA. The milk was diluted with phosphate buffer. The EIA was able to detect less than 1 ppb of paraquat in whole milk and down to 2.5 ppb in beef. The efficiency of HCl for extracting potato and ground beef was determined by using methyl-^{14}C paraquat. Recoveries between 60 and 70% were obtained. Since paraquat is known to bind tightly to many matrices, recoveries for both matrices were determined after storage of the spiked samples for several days at 21 °C.

Ibrahim et al.[233] investigated eggs for aldrin and dieldrin residues. An EIA with pAb was applied. The EIA detected only dieldrin, but aldrin is metabolized to dieldrin. The eggs were homogenized after removal of the shell. This solution was diluted 1 : 2 with wash buffer containing 2% BSA. Egg samples were collected in Egypt and assayed by EIA. The standard curve for dieldrin was prepared in egg solution of noncontaminated eggs. The egg samples showed concentrations of aldrin and dieldrin in eggs up to 0.7 $mg\,L^{-1}$. These are concentrations above the World Health Organisation average daily intake levels.

5.4 Biomonitoring

Human biomonitoring involves the measurement of a parent chemical and/or metabolites or a product of its reaction with cellular components (e.g. protein adduct, nucleic acid adduct) in selected tissues, body fluids such as blood, milk, urine or sweat, or expired breath of an exposed individual.[8,9] Most IAs for pesticides are sensitive enough for biomonitoring. Many analytes could be determined without any sample preparation other than dilution with water or buffer. In some cases the sample was filtered. Slightly reduced sensitivity or higher blank values due to matrix effects were sometimes found when the assay was performed directly in the biological sample. With increasing hydrophobicity of the analyte, sample preparation becomes more complicated.[8]

Validation experiments are carried out by fortification of samples with the analyte in question and comparison with independent control methods such as GC, GC/MS or LC. Samples from a number of individuals should be used in any validation experiment because of the inherent variability of biological matrices. Features such as pH, protein, sugar and salt concentration must be considered. Also the intake of drugs can interfere with the immunological determination of environmental pollutants.[8]

While many investigations were restricted to spiked samples only, some studies demonstrated the use of IA for surveillance of occupationally exposed individuals (e.g. for DDA, a metabolite of DDT, 2,4-D, paraquat and atrazine mercapturate).[140,171,234,235]

6 NEW DEVELOPMENTS

The strength of immunochemical methods lies in the screening of a large number of samples within a short time at low cost. Therefore, they can be valuable supplements to conventional analytical methods. Important applications are seen in the analysis of ground and drinking water, where matrix effects are seldom observed. Also, food commodities that turn over quickly are ideal targets for IA measurements. Owing to the low cost of one analysis more replicates from one site can be measured or special sites can be sampled more often, for example to obtain more information about variations of analyte concentrations depending on seasons or rainfall, etc.

Some restrictions are imposed by the fact that IAs are de facto single analyte methods. However, new approaches for multianalyte measurements are being undertaken, such as the integration of IA with LC. Here, Abs are used in conjunction with LC, e.g. to concentrate an analyte from a large volume of sample and separate it from an interfering matrix.[236–239] In this case an immunoadsorbent column is used before analysis by LC. The immunoadsorbent column contains immobilized specific Abs which bind the analyte, while interfering substances pass through. The analyte can be eluted by using a pH gradient[79] or an organic solvent.[80] Therefore, large sample volumes with low concentrations of the analyte can be reduced to small volumes with sufficiently high concentrations without coextracting interfering substances like HAs or food compounds. This raises the effective sensitivity of the analysis. Ab mixtures can be used to bind substances from different compound classes, e.g. the phenyl urea herbicides and the triazines.[239] In this case, the eluted compounds were injected into the LC, yielding a DL of 0.03–0.5 $\mu g\,L^{-1}$ from samples volumes as low as 25 or 50 mL.

When cross-reacting Abs are applied in IA, the signal obtained is not only related to the analyte, but also to similar compounds. This problem can be circumvented by the use of LC prior to the IA. LC/IA was applied by Krämer et al.[236] to determine 4-nitrophenols. The nitrophenols were separated by different LC systems and determined by IA. LC/IA was about 8–10 times more sensitive compared with LC with ultraviolet detection. Therefore, the integration of LC with IA combines the high separation quality of LC and the sensitivity of IA.[240,241]

Furthermore, multianalyte systems are under development. One concept is the microspot IA,[242] which uses many microspots with fluorescence-labeled Abs of different selectivity immobilized on a chip. After incubation with the analyte (Ag or hapten) a fluorescence-labeled tracer Ab is added. The tracer Ab is either directed against the Ag or consists of an anti-idiotype Ab directed against the binding site of the capture Ab. Sensor and tracer Ab carry different fluorescence labels. Therefore it is possible to determine the amount of analyte bound to the sensor Abs with optical scanning methods by measuring the signal ratio (ratiometric assay). Lately, a variety of noncompetitive and competitive microspot analysis systems have been developed, mainly related to the medical field,[243] but are clearly of particular importance in areas such as environmental monitoring.

Another possibility is the use of cross-reacting Abs for multianalyte detection. Known cross-reactivities of different Abs can be used to calculate the different concentrations of different analytes in a sample containing several contaminants.[244] The estimation of the individual concentrations is carried out by complex calculating procedures, e.g. by neural networks[245] or iterative procedures.[246]

Immunochemical analysis is a fast developing field with numerous possibilities for further improvement. Much effort is being put into the development of continuous measurements, such as flow-injection immunoanalysis (FIIA) and immunosensors.[247,248] A quasicontinuous FIIA of pesticides was developed by Krämer and Schmid[249] on the basis of a competitive IA. Here, the Abs are immobilized on a membrane. The reaction takes place in the membrane reactor, the central part of the flow injection system. All reagents are sequentially added to the reactor and the product is assayed with the aid of a flow fluorimeter. The measuring range of the flow injection analysis almost equals that of the EIA. Wittmann and Schmid[250] used an Ab column reactor filled with polystyrene or glass beads with the Ab immobilized via the avidin/biotin system. This system showed a stable Ab activity for a minimum of 500 measuring cycles. DLs for atrazine of about $1\,ng\,L^{-1}$ with pAb and $30\,ng\,L^{-1}$ with mAb could be reached.

Important progress is to be expected in the field of immunosensors where the detectors are based on Abs.[247] Some relatively simple devices such as dip sticks and immunofiltration assays have been mentioned before (see section 3.3). An interesting development is liposome-amplified immunomigration strips.[251,252] They employ liposome-encapsulated markers which act as signal enhancers of the competitive binding reaction instead of enzymes. These devices have been used for the determination of alachlor.[251] If a pesticide of interest is conjugated to a lipid it can also be incorporated into the liposome structure, leading to a competitive liposome IA.[253] In more complicated systems the immunological recognition system is immobilized in the direct vicinity of a transducer, an electrochemical, optical or gravimetric device. They respond to chemical compounds or ions and yield electrical signals which depend on the concentration of the analyte. Immunosensors with piezoelectric crystals as physical sensors are in a relatively advanced state of development.[254] They function as microbalances onto which Abs are immobilized. Other physical sensors use optical systems such as surface plasmon resonance (SPR), interferometry or grating couplers.[248,255,256] A biosensor employing SPR was used for the determination of atrazine.[256] A DL of $0.05\,\mu g\,L^{-1}$ for atrazine in water was reached with an analysis time of 15 min. Bier and Schmid[257] used a grating coupler immunosensor for the determination of terbutryn, a triazine herbicide. A DL of $15\,nmol\,L^{-1}$ (ca. $3.6\,\mu g\,L^{-1}$) was established. Interesting developments can be expected from Ab electrodes.[258]

New strategies for Ab production are also being developed. Genetically engineered Abs appear very attractive because their selectivity and affinity can be tailored by site-directed mutations without requiring new immunizations.[259] Methods are now provided to isolate desired clones rapidly from Ab libraries and to manipulate individual rAbs to match specific demands of environmental analysis. Binding proteins derived from Abs but consisting only of a part of their light or heavy chain (scFv, Figure 2) and rAb fragments, Fab, directed against different s-triazines, diuron and parathion have been produced.[260–264] In several cases the DL of the rAb was the same as with the parent mAb.[263,264]

A promising goal is the completely synthetic production of binding proteins or other synthetic receptors which are fitted to the structure of the analyte by molecular design. The use of libraries guarantees to close the bottleneck in Ab production. Abs with special properties such as resistance to matrix effects or organic solvent stability can also be selected from libraries, providing an important contribution to the analysis of water and food samples.

ACKNOWLEDGMENTS

I am grateful to Dr Armin Naß, Sension GmbH, Augsburg, for reading the manuscript and to Dr Sabine Pullen, Institute for Pharmacology and Toxicology, University of Erlangen, for providing some material on immunoassays for pesticides.

ABBREVIATIONS AND ACRONYMS

Ab	Antibody
Ag	Antigen
AOAC	Association of Official Analytical Chemists
BSA	Bovine Serum Albumin
CDR	Complementarity Determining Region
CLIA	Chemiluminescent Immunoassay
CV	Coefficients of Variation
DDA	Bis(*p*-chlorophenyl)acetic Acid
DDT	1,1,1-Trichloro-2,2-bis-(*p*-chlorophenyl)ethane
DL	Detection Limit
EIA	Enzyme Immunoassay
ELISA	Enzyme-linked Immunosorbent Assay
ESIMS	Electrospray Ionization Mass Spectrometry
Fab or $F(ab)_2$	Antibody Fragments Containing the Antigen Binding Site(s)
Fc	Antibody Fragment Containing the Crystallizable Fragment
FIA	Fluorescence Immunoassay
FIIA	Flow-injection Immunoanalysis
FR	Frame Region
GC	Gas Chromatography
GC/LC	Gas Chromatography/Liquid Chromatography
GC/MS	Gas Chromatography/Mass Spectrometry
HA	Humic Acid
HPLC	High-performance Liquid Chromatography
IA	Immunoassay
IC_{50}	Middle of Assay, Concentration of Analyte that Causes 50% Inhibition
Ig	Immunoglobulin
KLH	Keyhole Limpet Hemocyanin
LC	Liquid Chromatography
mAb	Monoclonal Antibody
MALDIMS	Matrix-assisted Ultraviolet Laser Desorption/Ionization Mass Spectrometry
MCPB	4-(4-Chloro-2-methylphenoxy)butyric Acid
pAb	Polyclonal Antibody
PCP	Pentachlorophenol
PFIA	Polarization Fluoroimmunoassay
rAb	Recombinant Antibody
RIA	Radioimmunoassay
scFv	Recombinant Antibody Fragment, Single Chain Fragment Containing only the Variable Region
SFE	Supercritical Fluid Extraction
SPE	Solid-phase Extraction
SPR	Surface Plasmon Resonance
2,4-D	2,4-Dichlorophenoxyacetic Acid
2,4,5-T	2,4,5-Trichlorophenoxyacetic Acid

Strategies for multiclass, multiresidue analysis of pesticides depend on several factors that all derive from three fundamental considerations: (1) the need for the results; (2) the form and composition of the matrix; and (3) the time, resources, and technology available to the analyst. First, the need for the data dictates the quality assurance (QA)/quality control (QC) guidelines and the desired analytical figures of merit, such as limits of detection (LOD) and the accuracy and precision of the results. These needs also contribute to the choice of pesticide analytes, which sets the polarity range for the analysis. No single method can determine all pesticides in diverse matrices, so an overall strategy is often used to compartmentalize a series of approaches in order best to detect the targeted pesticides in an effective and efficient process. Second, the various types of matrices that are commonly analyzed for pesticide residues may affect the sample preparation approach employed in the analytical strategy. Common matrices for pesticide analysis consist of solids, liquids, and gases in applications associated with food, agricultural, environmental, and other sample types. Varying degrees of pesticide–matrix interactions in different materials require more or less stringent extraction procedures to separate the pesticides from the sample. Sample preparation in multiclass, multiresidue strategies frequently utilizes liquid–solid, liquid–liquid and other partitioning processes including those, such as pressurized fluid extraction (PFE), in which pressure and temperature of different fluids are controlled. Extracts often require cleanup to remove interfering co-extracted matrix components prior to analysis. A variety of cleanup techniques based on a number of partitioning processes, such as liquid chromatography (LC), may be employed in an on-line or off-line fashion. Lastly, the sample extract is usually further separated and analyzed using one or more techniques. The majority of pesticides are analyzed by gas chromatography (GC) with mass spectrometry (MS) and/or element-selective GC detectors. High-performance liquid chromatography (HPLC) is often used in the analysis of thermally labile pesticides that are not amenable to GC analysis. Other alternatives for analysis of certain pesticide include capillary electrophoresis (CE) and immunoassays. Fundamentally, a high degree of selectivity helps in generating excellent analytical results, but the wide polarity range of analytes in multiclass, multiresidue methods (MRMs) for pesticides necessitates a great deal of effort to attain a high degree of selectivity. Trade-offs and compromises are omnipresent in multiclass, multiresidue analysis of pesticides, and a host of strategies are available depending on how the analytical chemist prioritizes the analytical and practical considerations.

1 INTRODUCTION

1.1 Reasons for Analysis

Pesticides are essential in agriculture to meet the food supply demands of the world. However, owing to notable transgressions that have occurred related to the dangerous use of pesticides harmful to human and ecological health, many people throughout the world have grown fearful of pesticides. Real and perceived concerns about pesticides have led to their strict regulation, and the need for a variety of analytical strategies in diverse applications.

The analytical strategy that is used for multiclass, multiresidue analysis of pesticides depends, in part, on the need for the results. Analytical methods are needed to monitor pesticide residue levels in food and other sample types, to help measure toxicological or other effects of

the pesticides on living organisms, and to discover the fate and transport of pesticides in plants, animals, and the environment. For quantitative risk assessment purposes, it is necessary to identify and quantify accurately a great number of pesticide residues at low levels (e.g. less than nanograms per gram). In other situations, it may only be necessary to screen rapidly for certain pesticides of concern at higher levels. Also, practical considerations, such as time, labor, instrumentation, and budget, although not formal analytical figures of merit, are frequently limiting factors in the type of approach chosen by a laboratory.

Many situations in the modern world require the screening, quantitation, and/or identification of pesticide residues in food, the environment, and other types of samples. Even before a potential pesticide product is developed and introduced into the market, manufacturers must have the means to isolate, analyze, and characterize the chemical in order to gain an understanding of its nature and effects. If the manufacturer decides to introduce the pesticide into the market, nearly all nations require that the pesticide be approved (or registered) for specified uses in their country or group of countries. One common facet of the pesticide registration process requires that acceptable analytical methods be available, or that new methods be developed, for the parent pesticide and potentially harmful transformation products or coformulants.

Pesticide manufacturers are usually required to test the utility of common MRMs when applying for registration of a new pesticide. In the USA, the MRMs for foods are published in the *Pesticide Analytical Manual*, Vol. I (PAM I).[1] However, for a new pesticide, the PAM I MRMs may fail to achieve adequate recovery (typically >70%) or detection limit (less than half of the regulatory limit) for reasons related to the nature of the pesticide, matrices of interest, the need to detect metabolites, and/or an inability to modify the PAM I methods. In this case, the manufacturer must develop a new method, which will likely be a single analyte method specific to the pesticide and commodity of interest. In the USA, these methods are published in the *Pesticide Analytical Manual*, Vol. II (PAM II).[2] Modification of a multiclass, MRM or the development of a new method to widen the analytical range may be possible, but the manufacturer has little incentive to develop such an approach which could take much time and effort, benefit its competitors, and lead to greater enforcement monitoring of the product once it reaches the market. In general, single analyte methods in PAM II are complicated, rapidly outdated, and infrequently used in monitoring of pesticide residues owing to the cost of conducting many separate analyses. However, the use of multiclass, MRMs usually provides the most efficient approach for pesticide analyses.

Individual governments and international bodies, such as the Codex Alimentarius, commonly set maximum residue limits (MRLs), which are known as tolerance levels in the USA, for pesticides in food commodities and other matrices, such as water, which may be exposed to pesticides. Proper usage of pesticides is enforced, in part, by periodic monitoring of pesticide residues in collected samples. Nearly all governments worldwide (national and often local) conduct multiresidue pesticide analysis for food and other matrix types. A stipulation in international trade is that imported foods must not contain violative levels of pesticide residues. Thus, food imports are often tested at a higher sampling rate than domestic products, as included in Table 1. Furthermore, it is not unusual for

Table 1 Number of food samples analyzed for multiple pesticide residues from selected monitoring and compliance programs

Country/program[a]	Year(s)	No. of samples	Commodities	Imports (%)[b]
US (Federal):				
USDA Pesticide Data Program	1997	8177	Produce, grains, milk	13
FDA Total Diet Study	1997	1036	Many types	–
FDA Surveillance and Monitoring Program	1997	9843	Many types	54
USDA Food Safety Inspection Service	1996	7705	Meat, poultry	–
Canada: Food Inspection Agency	1992–1994	~7300/year	Fruits and vegetables	73.7
UK: Ministry of Agriculture, Food, and Fisheries	1996	3665	Many types	39
Sweden: National Food Administration	1997	~3750	Fruits and vegetables	NR
Finland: National Food Administration	1997	2479	Fruits and vegetables	77
Norway: monitoring program	1996–1997	>5940	Fruits and vegetables	NR
Netherlands: Inspectorate of Health	1997	~10 000	Agricultural products	NR
Spain: Ministry of Agriculture and Fisheries	1995	3051	Produce	NR
Italy: monitoring programs	1992–1997	>10 400/year	Food products	NR
Switzerland: cantons	1994	7945	Many types	41
Germany: food monitoring program	1995	~5000	Many types	50

pesticide or other types of residues to be used as a trade barrier or hurdle to help protect domestic markets.

Many industrial and academic purposes also necessitate the analysis of pesticides. For example, food processors, or their contract laboratories, often perform testing to ensure that pesticides do not occur in their products at adulterating amounts. Toxicologists, ecologists, agricultural and environmental scientists, and several others also require the multiclass, multiresidue analysis of pesticides in many types of studies. Individuals, consumer groups, and environmental organizations may also hire contract laboratories to analyze pesticides in various types of samples for a number of reasons. Additionally, the continuing rapid progress being made in analytical instrumentation and techniques have led to a great deal of method development and evaluation studies which involve the analysis of a large number of samples. Analytical methods approved by the US Environmental Protection Agency (EPA) for pesticides and other contaminants in environmental samples have been published.[3]

Estimation of the number of multiclass, multiresidue analyses of pesticides that are performed yearly around the world is difficult. Essentially, only analyses performed by government agencies in their food monitoring and compliance programs are published, and Table 1 lists the number of analyses reported by selected countries. Many more samples are analyzed than those presented in Table 1, and it is safe to estimate that >150 000 multiresidue pesticide analyses are performed by governments and industry yearly worldwide.[4]

1.2 Matrices

A variety of matrices are regularly analyzed for pesticide residues. These matrices can be broadly divided into ''environmental'' and ''food and agricultural'' sample types. Environmental samples can be divided into air, water, and solids (soils, sediments, particles, sludges, nonanimal solid wastes, and surfaces). Plant, animal, and fungi samples, including bodily fluids, may be taken for clinical, environmental, or other purposes, but owing to their similar compositions as some foods, they will be classified as ''food and agricultural'' samples. Therefore, ''food and agricultural'' items essentially consist of all edible and nonedible organisms, tissues, and products from organisms. Examples include fruits, vegetables, grains, nuts, beans, fish, meats, meat byproducts, eggs, poultry, animal feed, dairy products, beverages, spices, honey, mushrooms, processed foods, dried fruits, tobacco, plant tissues, bodily fluids, animal waste, and a host of other materials (drinking water will be regarded as an environmental water sample rather than a beverage). For purposes of residue analysis, food and agricultural matrices can generally be divided based on their composition, particularly with regard to water and fat content.

1.2.1 Food and Agricultural Samples

Because agricultural applications make up the largest area of use for pesticides, and food safety is such an important concern, foods are a widely analyzed matrix type for pesticide residues. Raw commodities, such as fruits and vegetables, are often the most appropriate food items in which to monitor pesticides because they are generally ready for consumption nearest to the times of pesticide applications and typically have the highest residue concentrations.

Foods are often complex matrices with widely varying compositions, but many foods consist of four major components: carbohydrate, fat, protein, and moisture. A fifth component, ash (or mineral composition), is rarely >5%. Of the four major components, carbohydrates include sugars, starches, oligosaccharides, and fibers; fat includes mono-, di-, and triglycerides, oils, fatty acids, and sterols; protein includes all organonitrogen components (amino acids, enzymes, etc.), and moisture is essentially water content.[5] For nutritional labeling purposes and simplicity, food chemists have deleted water from consideration and developed a diagram, as shown in Figure 1, to help categorize foods based on the relative compositions of proteins, lipids, and carbohydrates.[6] Figure 1 contains nine smaller equilateral triangles to serve as representational sectors in which similar food types appear (some examples of the relative compositions of different foods are provided in the diagram). USDA provides a Nutrient Database that is accessible in searchable format on the internet and currently lists the compositions of about 6000 food items.[7]

Figure 1 Major composition of foods. [Reprinted from Wolf.[6]]

The capability of analytical methods can be matrix dependent, but the great variety of foods limits practicality to validate new analytical methods for all food matrices. For this reason, scientists within the Association of Official Analytical Chemists (AOAC®) International have proposed that one type of food within a sector could serve as a reference for other types of foods within the same sector, particularly for methods to measure food composition.[8] For example, investigators in one study involving nonfatty foods chose 27 pesticides in six matrices (apple, carrot, spinach, strawberry, tomato, and wheat) to represent the broader scope of pesticides and commodities in a comparison of different multiclass, MRMs of analysis among 24 laboratories.[9,10]

For residue analysis and other purposes, the FDA has categorized and coded many different food products, which are summarized in PAM I.[1] Table 2 provides ranges of % fat, % water, and % sugars of selected commodities. In broader terms, the FDA separates analytical methods that are applicable to fatty (>2%) and nonfatty (<2% fat) foods. Further demarcations can be drawn based on % water or % sugars, but it is easy (and sometimes necessary) to add water[1] or sugars to the matrix during sample preparation, whereas fats are never added. There are instances when the addition of sugar helps in a liquid–liquid partitioning step, and the presence of water in an analytical procedure can be a critical benefit or detriment depending on the application. Thus, rather than devising a number of different strategies depending on the matrix, it is possible to limit the number of necessary methods by forcing the matrix to suit the method. Similarly, some analytical methods may include procedures, such as gel permeation chromatography (GPC), that are able to remove fats from sample extracts even though the samples may not contain fat. This concept is not necessarily the most efficient, but it does limit the number of different methods needed in the overall strategy for diverse matrices.

Table 2 Composition of selected food commodities [from Food and Drug Administration[1]]

Commodity	Fat (%)	Water (%)	Sugars (%)
Fruits	0.1–1	80–95	5–18
Vegetables	0.1–1	80–95	1–7
Rice	1.1	7.8	2.5
Lima beans	0.7	10.2	8.5
Whole milk (cow)	3.7	87.7	4.9
Soybeans	19.9	8.5	6.6
Peanuts	49.2	6.5	4.3
Mushrooms	0.4	91.8	1.8
Oyster	2.5	85.1	0
Fish, sturgeon	4.0	76.6	0
Avocado	17.3	72.6	0.9
Honey	0	17.2	81.9

Fatty foods are known for their greater difficulty in analysis owing to smaller differences in the polarity of lipids from many common pesticides. Furthermore, greater importance is often placed on the analysis of lipophilic pesticides, such as organochlorines, in fatty foods because those pesticides may be persistent, bioaccumulative, and/or pose higher human health or ecological risk. Nonlipophilic pesticides do not accumulate in animal tissues, hence there is less need to monitor for them in fatty matrices.

Nonfood plant and animal tissues can often be treated in a similar fashion to food items based on their composition; however, the nutrient compositions of tissues inedible to humans are not as well documented. Also, the cell walls and exoskeletons of plants and animals not generally eaten by humans often require more effort to rupture during extraction than the techniques used for food items. For example, longer extraction times, acid–base conditions, and/or higher temperatures may be needed. Furthermore, more complications in analysis can occur owing to the potential interference of natural compounds developed in defense and other evolutionary processes. For these reasons, in part, it is common for analysts to devise single analyte or single class residue methods for unique matrices. In some matrices, it may be impossible to achieve sufficiently low detection limits and high recoveries for a wide polarity range of pesticides with traditional multiclass, MRMs.

1.2.2 Environmental Samples

1.2.2.1 Water Environmental water samples consist of drinking water, surface and groundwater (salty or fresh), precipitation, ice, process streams, waste effluents, and other aqueous media. Water is generally considered an easy matrix for pesticide residue analysis because it often contains few interferences and is usually sampled as a homogeneous liquid. Water samples are often filtered to remove suspended particles which allows the separate determination of dissolved analytes from those associated with the particle phase. Very low detection limits can be achieved by concentrating extracts from large sample volumes. However, some water samples with high concentrations of organic substances, such as marsh water or waste streams, may require cleanup of the extracts. Solid-phase extraction (SPE) has become the primary means to extract and cleanup water samples.

1.2.2.2 Solids Soils, sediments, sludges, compost, particles separated from water and air, surfaces, and other solid environmental materials can be categorized as environmental solid sample types. Sediment is essentially

the same as soil except that it occurs underwater; sludge is the waste material that settles in waste treatment plants or other facilities. Soils and other environmental solids tend to have much stronger adhesion and/or other forms of chemical interactions than other types of matrices. An unsettled issue among pesticide residue chemists is whether special measures should be taken to extract bound residues that are covalently or otherwise strongly infused with the matrix.[11] In the pesticide registration process in the USA, the EPA requires that a ^{14}C-labeled analyte be used in method development studies to determine the total extractability of the pesticide in the targeted matrices. In the case of soils, the extraction process of pesticides often requires stronger measures (sonication, longer extraction times, acid–base conditions, repetitive steps, and/or higher temperatures) than in the case of food samples.

The variability of soils is very high, and just as nutritionists have characterized foods by protein, carbohydrate, and fat (Figure 1), soil scientists have developed a textural classification diagram for soils based on sand, silt, and clay content (Figure 2). The classification boundaries and nomenclature of soil types appear in the diagram (loam is a mixture of sand, silt, and/or clay). According to USDA definitions, sand (and gradations thereof) has particle sizes between 0.05 and 2 mm, silt particle sizes are between 0.002 and 0.05 mm, and clay consists of particles smaller than 0.002 mm.[12] Sand separates (very fine, fine, medium, coarse, and very coarse) are determined by sieving, and silt and clay are differentiated by their settling rates in water. Particles larger than 2 mm, which have little bearing on either soil properties or analytical residue methods, are considered as stones or gravel and are excluded from the textural classification.[12]

Figure 2 Textural diagram of soil. [Reprinted from Troeh, Thompson.[12]]

As in the case of the food classification diagram, water is not represented in the soil textural diagram even though it can be a major constituent. The organic content of soils, which can be likened to the many potential analytical interferents in food and agricultural samples, is also an important component that is left out of the diagram (the organic content is usually a low percentage overall). However, water, salts, pH, and organic content can all have major effects in the analysis of pesticides in soils, sediment, sludges, compost, and suspended particles.

Other types of solid samples that may be analyzed for multiple types of pesticides include exposed surfaces. Flooring, counters, and other surfaces may be sampled by rinsing or wiping with solvents to test for effectiveness and legality of pest control in homes and businesses, and clothing, skin, hair, and similar materials may be sampled in the study of occupational or other cause of exposure to pesticides. Also, it is sometimes necessary to test container surfaces to determine unknown types of pesticides that may have been present previously or to study the effectiveness of a cleaning process. Similarly, multiclass, MRMs are needed to identify unlabeled pesticide formulations or waste materials of unknown origin.

1.2.2.3 Air Owing to the nature of the gaseous medium, air samples require very different approaches, particularly in the sample collection process, to those employed for solids and liquids.[13] Sample volumes are determined by flow rates, time, temperature, and pressure, which must be known to convert volumes to standard conditions. Collection of fog and suspended particles in air also requires unique procedures, but once air or samples from the air have been collected, cleanup steps are rarely required. Typically, the sample extracts are concentrated in a liquid or solid-phase trap and injected directly into a GC column for analysis. LC is generally not used owing to the nature of typical pesticide analytes found in air and more complicated injection procedures for air samples. Constituents from very high volumes of air can be concentrated by trapping to achieve exceptionally low detection limits (below the nanograms per cubic meter level).

1.3 Pesticides

The diverse range of purposes and sample types for pesticide analysis is only matched by the diversity of chemicals to be analyzed. There are numerous sources of information on the chemistry, applications, and regulation of pesticides.[14–17] A brief review of fundamental aspects of pesticides is provided in the following paragraphs.

The term ''pesticide'', as defined by the EPA, broadly represents ''any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest''. These pests can be divided into categories such as weeds, insects, arachnids (mites and ticks), fungi, slugs, nematodes (a type of worm), rodents, microorganisms, and miscellaneous other pests, which form the basis for the more specific terms, ''herbicides'', ''insecticides'', ''acaricides'' (or ''miticides''), ''fungicides'', ''molluscicides'', ''nemiticides'', ''rodenticides'', and ''antimicrobial pesticides'' (and ''biocides'' or ''disinfectants''). Pesticides also generally include fumigants, sterilants, growth regulators, defoliants, repellents, and synergists (compounds that aid action of a pesticide). For the purpose of simplicity, the term ''insecticide'' is commonly used to include all pesticides used for control of animal pests, ''herbicide'' includes plant growth regulators, and ''fungicide'' can also refer to chemicals used in noninsecticidal postharvest applications (e.g. antiscalding).

In strict terminology, broader or narrower terms have been devised, such as ''agrochemical'' (to include fertilizers and other compounds of agricultural significance), or ''crop protection agent'' (to differentiate agricultural and nonagricultural uses of pesticides), but sometimes other terms, such as ''plant protection product'', are used to avoid the word ''pesticide'' for public perception reasons. Pesticides also include natural chemicals used for pest control, but these are sometimes called ''alternative'' or ''natural'' pesticides to distinguish them from synthetically derived pesticides.

Agricultural usage of pesticides constitutes the largest application sector, but home, business, and other pest control applications are also significant. The USDA National Agricultural Statistics Service (NASS) provides annual reports, which are accessible through the Internet, concerning pesticide usage on field crops in the USA.[18] Herbicides are the most heavily used pesticides in agriculture, followed by insecticides, then fungicides. Agricultural applications of pesticides can be further divided into preplanting, preemergent, preharvest, and postharvest in the case of plant products, or preslaughter and postslaughter in the case of livestock.

Pesticides are either inorganic or organic chemicals, but usually different analytical methods are used to detect inorganic compounds to those used for organic analytes. Inorganic pesticides, which can be herbicides, insecticides, and/or fungicides, include compounds and salts containing arsenic, copper, sulfur, mercury, or other metals (organometallic pesticides are considered organics). However, only organic species are generally analyzed in multiclass, MRMs for pesticides, and the inorganic pesticides are typically analyzed in foods and the environment separately using elemental detection methods. A few approaches, such as atomic emission detection (AED) after GC, may be able to analyze organometallic species in the same procedure as other classes of pesticides,[19] but it is more common to have separate methods for organometallics.

1.3.1 Herbicides

Table 3 presents major classes of herbicides, their solubility range in water, common examples of individual herbicides within each class, and their basic chemical structures. Many herbicides are applied early in the agricultural season and generally dissipate rapidly. Furthermore, more recently introduced herbicides, such as sulfonylureas and imidazolinones, tend to have selective weed-control properties, pose little toxicological threat to animals, have relatively low application rates, and degrade rapidly.[20] Few herbicides appear as residues in foods, and many are not commonly included in multiresidue, multiclass methods. Those which have longer environmental persistence than a few months, such as some triazines and acetamides, can typically be recovered and detected at low levels (nanograms per gram) using many current multiclass, MRMs, and are frequently included in analyses, but they are still rarely found in foods.[21] However, heavily applied and relatively stable herbicides, such as triazines, are frequently found in environmental water and soil/sediment samples.[22]

Owing to the relatively high polarity and often ionic nature of many herbicides, they are more prevalent in water and soil samples than in food and air matrices. Owing to the nature of the analytes, the development of multiclass, MRMs for polar/ionic herbicides is more difficult than in the case of less polar pesticides. Instrumental approaches, such as HPLC or CE, may permit the simultaneous analysis of multiple polar/ionic herbicides,[23,24] but few cleanup techniques allow the recovery of a wide range of polar analytes in complex matrices.[25] Hence, typical multiclass, MRMs for polar herbicides are generally only useful for relatively clean aqueous matrices.

1.3.2 Insecticides

Many insecticides are also used as acaricides, nematicides, and rodenticides, and vice versa. A few herbicides (dinitrophenols) and fungicides (organotins) may also have insecticidal activity, and the categorization of pesticides can depend as much on how a pesticide is used as its chemical class. Table 4 lists the major classes of insecticides on the basis of relatively similar chemical structures. In some classification schemes, the elemental composition of the pesticide determines its category, such as organophosphorus, organonitrogen, organosulfur, and

Table 3 Major classes of organic herbicides and examples

Class	Solubility range in water (mg L^{-1})	Examples	Basic structure
Acetamide	10^2–10^4	Alachlor, metolachlor	Chlorophenoxy	10^1–10^6	2,4-D, 2,4,5-T, MCPA, silvex	Dinitroaniline	10^{-1}–10^0	Pendimethalin, trifluralin, dinitramine	Imidazolinone	10^1–10^6	Imazaquin, imazapyr, imazethapyr	Phenylphenoxy	10^{-1}–10^6	Fomesafen, bifenox, fluazifop-butyl	Phenylurea	10^0–10^3	Linuron, diuron, thidazuron, neburon	Sulfonylurea	10^2–10^4	Chlorsulfuron, chlorimuron-ethyl	Thiocarbamate	10^0–10^6	Vernolate, asulam, butylate, thiobencarb	Triazine	10^0–10^4	Atrazine, ametryn, simazine, prometon	
Table 4 Major classes of insecticides

Class	Solubility range in water (mg L^{-1})	Examples	Basic structure
Carbamate	10^1–10^5	Carbofuran, aldicarb, propoxur, oxamyl	Organochlorine	10^{-3}–10^0	Methoxychlor, DDE, lindane, endosulfan	Insecticides containing chlorine
Organophosphorus	10^{-1}–10^6	Diazinon, chlorpyrifos, acephate, ethion	Pyrethroid	10^{-3}–10^{-1}	Permethrin, cyfluthrin, fenvalerate, bifenthrin	Similar to 
organochlorine (or organohalogen). This classification approach is useful when considering which type of elemental selective detector in GC can be used, but the pesticides within these categorizations are not necessarily recovered through the same extraction and cleanup approaches. Also, there is considerable overlap for many pesticides that contain more than one of these elements. Both of these circumstances are also true for chemical structural classification schemes, but there is less overlap.

Chlorinated hydrocarbon and cyclodiene insecticides, widely known as organochlorine pesticides (OCs), are the most widely analyzed pesticides in the most matrix types. They are most commonly detected in fatty and nonfatty foods, soils/sediment, water, and animal and plant tissue samples. Nearly all OCs were banned in industrialized nations during the 1970s, and essentially only endosulfan and dicofol, which are less persistent and pose less risk than the others, are still commonly used in these countries today. However, many of the banned OCs are still applied in several developing countries to combat malaria and other insect-borne diseases. In environmental and epidemiological studies, analytical methods often target OC insecticides along with polychlorinated biphenyls, polycyclic aromatic hydrocarbons, and other nonpolar contaminants in a similar or the same general approach.

Organophosphorus insecticides (OPs) are currently the most widely used insecticides, but they are less frequently monitored in environmental samples than the OCs owing to their lower persistence. In nonfatty foods, OPs are detected more frequently than OCs, and their residue concentrations are typically slightly higher, whereas the opposite is true in the case of fatty foods. The variety of OPs and their different uses are unmatched among all pesticide classes.

Carbamate insecticides, which are sometimes called *N*-methylcarbamates to distinguish them from (thio/phenyl) carbamate herbicides and (dithio)carbamate fungicides, are also frequently used in agricultural and home applications, but there are fewer carbamate insecticides than OPs. A few of the thermally stable carbamates (propoxur, carbofuran, and carbaryl) can be analyzed by GC methods, but a separate HPLC procedure is more commonly conducted for the simultaneous analysis of *N*-methylcarbamates.[26] HPLC can also be used for the simultaneous analysis of OPs along with carbamates and other pesticides, but capillary GC provides superior separations and more sensitive detectors for the numerous OPs. The use of single class, or selective, MRMs such as methods for carbamates, benzimidazole fungicides, phenylurea herbicides, and others are often incorporated into an overall multiclass, multiresidue strategy.[1,22]

Owing to recent studies on neurotoxic effects of cholinesterase-inhibiting insecticides (OPs and carbamates), especially with respect to infants and children,[28] there is currently much discussion among scientists, environmental groups, farmers, the chemical industry, regulators, and politicians about whether the use of OPs should be curtailed. For this reason, regulatory and risk assessment needs have further emphasized the detection of OP and carbamate pesticides at ultratrace levels in all matrices to which humans are exposed.

Pyrethroid, nicotinyl, alkyloid, and rotenone insecticides are either synthetically derived from naturally occurring compounds produced by plants in defense from pests or isolated from organisms themselves. The pyrethroids constitute the most widely used of these classes currently, and their use is expected to grow if the prevalence of OPs decreases. The human health risk of pyrethroid pesticides is lower than that of OPs but they commonly have higher acute toxicity to fish and other aquatic species. In the future, several other chemical, physical, and biological pesticide alternatives may help to reduce the reliance on many of the current commonly used insecticides.

1.3.3 Fungicides

Table 5 lists common fungicide classes and their basic structures. Some fungicides are used in preharvest applications to control fungi in the soil or above ground on plants. Other fungicides are used in postharvest applications to improve product quality or extend shelf-life. The fungicides that are used in postharvest applications are the most commonly found in fresh produce, and their concentrations can be much greater than those of other residues.[21] Therefore, multiclass, multiresidue strategies for foods often include several fungicides in the approach, but several organonitrogen fungicides (azoles, imides, etc.) can be problematic in the procedures. However, there is little toxicological risk of approved postharvest fungicides to animals. Tolerances or MRLs for several postharvest fungicides are $>5\,\mathrm{mg\,kg^{-1}}$ in fresh commodities, which can be more than 100-fold higher than some higher risk insecticides.[21]

Postharvest fungicides are rarely expected to occur in environmental samples, and few environmental methods look for them. However, some preharvest fungicides may be found both in the environment and in foods. OC fungicides, such as chlorothalonil and quintozene, and transformation products are sometimes also included in multiresidue, multiclass analyses of environmental samples.

The widely used dithiocarbamate fungicides are not analyzed with the same methods as other pesticides owing to their chemical instability and unique properties.

Table 5 Major classes of fungicides

Class	Solubility range in water (mg L^{-1})	Examples	Basic structure
Dithiocarbamate	10^{-1}–10^{5}	Mancozeb, maneb metriam, zineb	Imidazole	10^{0}–10^{4}	Carbendazim, imazalil, thiabendazole	
Phthalimide	10^{0}	Procymidone, captan, captafol, folpet	Triazole	10^{1}–10^{3}	Myclobutanil, propiconazole	

A common strategy is to digest the dithiocarbamates to form either ethylenethiourea (ETU) or CS_2 for detection.[29] The result represents a summation of all dithiocarbamates, but the chance of inaccurate results is substantial owing to natural sources of compounds that also produce ETU or CS_2 in the approach. Extraction with a basic buffer and ethylenediaminetetraacetic acid (EDTA) followed by ion-pairing HPLC can determine individual dithiocarbamates.[30]

1.3.4 Pesticide Properties

In any analysis, the physicochemical properties of the analyte(s) determine the type of possible approaches that lead to a successful extraction, cleanup and detection procedure. An important aspect is the polarity of the analyte, which can be estimated for the purposes of this article through its solubility in water and/or its octanol–water partition coefficient (K_{ow}). In the analysis of pesticides that are weak acids and bases, pH and ionic strength also become critical aspects in the approach. Other factors of note include volatility and stability, which indicate what precautions must be made to avoid analyte losses.

Several chemical properties of interest for many pesticides are listed in the USDA Pesticide Properties Database,[31] which is also accessible on the Internet (http://www.arsusda.gov/rsml/ppdb.html). Figure 3 includes the 353 pesticides in the database categorized by their solubilities in water which broadly indicate the number of pesticides with a particular polarity range. Tables 3–5 provide the water solubilty ranges of the different pesticide classes listed in the database. The majority of pesticides are considered to be semipolar, with solubilities in water of ~1–10 mg L^{-1}, as can be seen by the profile in Figure 3, but many pesticides, generally herbicides, tend to be rather polar with solubilities in water >100 mg L^{-1}. Polar pesticides are typically more

Figure 3 Polarities of pesticides in the Pesticide Properties Database as estimated by their solubilities in water. [Reprinted from Lehotay.[61]]

problematic in multiresidue analysis, but they also tend to be less toxic to humans and less persistent in the environment. However, analytical strategies for less polar pesticides are fairly straightforward. The inclusion of polar pesticides increases the difficulty in the analysis and, in practice, it is more common to have separate methods for the most polar pesticides owing to their more unique characteristics. Even polar pesticides with the same solubility in water at a given pH may behave much differently in a particular approach owing to different functional groups, which is a less frequent problem for nonpolar and semipolar pesticides.

1.4 Quality Assurance and Quality Control

QA and QC overviews have been published.[33,34] For pesticide residue monitoring of foods, a working group of the European Union (EU) recently published their recommended QA/QC guidelines.[35] QA is the process to help ensure the quality of results using any analytical

method, and QC represents the provisions taken for a particular set of samples, such as blanks and spikes, to help verify the quality of the results of that sample set.

QA/QC standards should be set to meet the needs for the results. For example, strict standards are used when the most accurate and precise results are needed, and looser standards may be used when rapid screening or general surveillance is being conducted. Very accurate and precise results meet the needs of all applications, but often the sample throughput, cost requirements, or analytical difficulties limit the ability to always obtain results of the highest quality. A balance in the worth of the results versus the cost of obtaining them should be sought.

In recent times, QA guidelines have been expanded to more holistically incorporate laboratory functions, and the term good laboratory practices (GLP) has emerged. GLP is a process to ensure that proper procedures are followed within the laboratory to achieve results of acceptable quality. GLP includes such factors as having a QA manual and officer, developing and following standard operating procedures (SOPs), training and certifying analysts, periodically checking and recording freezer temperatures, regularly calibrating balances, and several other functions.[36] GLP, in turn, has led to the next step for a laboratory, which is to obtain accreditation for a particular analysis by an independent accrediting body. The standards that are followed for laboratory accreditation have been debated among different organizations for many years, but recently, ISO 25 criteria devised by the International Standards Organization (ISO) have begun to be generally accepted.

1.4.1 Method Validation

Analytical methods must be validated through repetitive recovery studies of fortified samples and, depending on customer requirements and analytical needs, these studies may need to be performed in a minimum number of different laboratories. In the case of pesticide residue analysis, pesticide recoveries of 70–120% in matrix spikes using three replicates each at 2–3 different concentrations are generally acceptable. Depending on the concentration, the variability of the recoveries should be <20% relative standard deviation (RSD). Furthermore, methods must be capable of attaining the desired limit of quantitation (LOQ) which may be checked by spiking samples at this level. Some organizations require laboratories to submit only those results that have been obtained using prescribed methods that have undergone interlaboratory method validations.

The AOAC® International is an organization that is involved in the certification of analytical methods through interlaboratory collaborative studies in the analysis of shared samples. For a method to obtain AOAC® Official Methods or Peer Verified status, defined procedures are followed and certain statistical criteria for the results must be met.[37] Interlaboratory validations for any method can be time consuming, laborious, and expensive, and subsequently a good method may still give inconclusive results in the study for a variety of reasons. The effort required to carry out a multiclass, multiresidue collaborative study is substantial, and to consider all analytes and matrices is practically impossible. Since 1980, only a single multiclass, MRM for pesticide residues in foods has been evaluated and attained Official Method status.[38] The collaborative study, conducted in 1984, involved only six pesticides in three fruit and vegetable matrices.[39] Another collaborative study was attempted only recently and the results were acceptable for nearly all of the 13 fortified pesticides evaluated in 3 commodities.[40]

The rigorous requirements and great effort to perform interlaboratory validations have tended to stifle the implementation of new approaches for official monitoring purposes. It often takes many years for a new, advantageous technique to achieve general use, in part owing to stringent, impractical, or incompatible method acceptability parameters. For this and other reasons, the concept of performance-based measurement systems (PBMS) is common for multiclass, MRMs. PBMS relies on internal laboratory method validation results and QA/QC protocols to verify that the quality of analytical results is satisfactory. The proliferation in the use of proficiency testing, or blind check samples, has made it possible to determine the quality of results from a laboratory, analyst, and/or method in a situation reasonably close to real-world analysis. In some laboratories, check samples are prepared regularly by the QA officer, and more widespread programs have developed among a group of laboratories or in a fee-based service.[41]

The proficiency test samples may contain naturally incurred residues in addition to those spiked into the matrix. One of the problems with the use of only spiked samples in method validation is that the pesticides are not incorporated as strongly into the matrix, so higher recoveries may be achieved for the spiked samples than real-world samples. However, results from studies involving the analyses of proficiency test samples indicate that several different methods can achieve equally valid results for many pesticides in food matrices.[9,10,41]

The lack of a known concentration for incurred residues has made the determination of accuracy somewhat questionable, but comparison of results using different methods is useful. Standard reference materials are available for certain OCs in animal tissues[42] or environmental solids to help verify analytical methods, but none have been developed for other types of pesticides. An attempt to develop a reference material for pesticides in grain determined that inadequate stability of the pesticides,

inhomogeneity of the samples, and variability in the results made the attempt unsuccessful.[43] The comparison of results for shared samples has become a means by which new methods are commonly validated.

1.5 Strategies

Usually, the most efficient overall analytical strategy for a laboratory to reduce time, labor, and cost is to use the fewest possible methods for the most analytes. An inherent difficulty with multiclass, MRMs is that as the polarity range of analytes increases, more matrix co-extractives and potential interferences occur. No current method can analyze for all pesticides from all matrices with a single approach. Therefore, the overall analytical strategy depends on how the chemist decides to compartmentalize the range of analytes and matrices to be analyzed. The strategy is constrained by the laboratory budget/resources, among other factors, but it must still meet the QA criteria determined by the need for the data.

The majority of nonpolar and semipolar pesticides do not pose much trouble in analysis, and many techniques can achieve high-quality results for stable OCs, OPs, and similar compounds. The challenges and main differences in approaches occur for those problematic pesticides that are more volatile than the others, tend to degrade, possess matrix-dependent interactions, interfere in the detection of another pesticide, or stick to glassware, among other possibilities. For best results with problematic pesticides, single-analyte or single-class methods may be more appropriate,[1,27,44] but this is not commonly possible in laboratories owing to the added effort and cost. The multiclass, multiresidue strategy within a laboratory should be developed to minimize cost and maximize convenience for the pesticides and matrices of interest while still meeting the needs for the results.

Figure 4 illustrates the monitoring strategy used by laboratories of the General Inspectorate for Health Protection in The Netherlands for the analysis of pesticide residues in fruits and vegetables. The ''Dutch approach'' is probably the most streamlined and cost-effective strategy implemented for a wide range of pesticide residues in fruits and vegetables, and it has been extensively evaluated.[27]

However, the multiclass, multiresidue analysis of pesticides is a constantly evolving process. New pesticides, instruments, and techniques are frequently introduced, and continually changing priorities, budgets, and analytical needs compound the problem. Many chemists in many monitoring laboratories around the world are striving to devise the optimal approach. Even well-established methods are modified frequently, and few laboratories follow methods exactly as published in the literature, even those in which the published methods were originally developed.

Figure 4 Current overall strategy of the Dutch multiclass, multiresidue analysis of pesticides in foods. HPLC methods: 1, *N*-methylcarbamate insecticides; 2, benzimidazole fungicides; 3, phenylurea herbicides; 4, benzoylphenylurea insecticides; 5, conazole fungicides. ITD, ion-trap detector. [Reprinted from A. de Kok, M. Hiemstra, presentation at the 2nd European Pesticide Residue Workshop, Almerìa, Spain, May 24–27, 1998.]

For example, Milton Luke of the FDA, the originator of the ''Luke'' method,[45] has spent many years altering and optimizing the method named after him. In another case, Fillion et al. altered their primary multiclass, MRM used in the Canadian Monitoring Program in order to utilize new SPE cartridges in the market.[46] Furthermore, the chemists in the Inspectorate of Health in The Netherlands took much time and effort to validate their current suite of methods as part of their overall analytical strategy, and they will likely spend several years in the future developing and validating new methods that take advantage of the improvements offered by recent advances in liquid chromatography/mass spectrometry (LC/MS) and other technologies.

Invariably, trade-offs and compromises are required in any multiclass, multiresidue strategy, and not all analytes will be recovered completely for detection at low levels in all matrices. Each approach may possess advantages and disadvantages with respect to certain pesticides, matrices, and practical aspects (convenience, costs, time, space, etc.). There are so many different variations in the analysis of pesticide residues that it is practically impossible to present them all. Thus, only major differences in the analytical process (sample preparation, analytical separations, and detection) will be presented in this article. Recent review articles for pesticide residue analysis can be found in a number of publications.[47–50] Table 6 lists and compares different methods of analysis

Table 6 Comparison of multiresidue extraction methods

Parameter	FDA[51]	CDFA[52]	Swedish[44]	Canadian[53]	Dutch[27]	SFE[40]

CDFA, California Department of Food and Agriculture; Current FDA, CDFA, and Canadian methods have been modified slightly from publications. SFE, supercritical fluid extraction; ODS, octadecylsilane; QMA, quaternary methylamine.

[a] Costs vary depending on vendors; other costs not presented include labor, instrumentation, and indirect charges.

for multiple pesticide residues fruits and vegetables. Minor modifications of these methods (except in the case of the SFE method) often permit the analysis of fatty foods, and these methods are often also applicable to other matrices. Analytical methods commonly used for water, soil, sludge, and other environmental matrices have been published.[3,54]

2 SAMPLE PREPARATION

All aspects in the analytical process are equally important, and no step can improve upon the quality of the previous step in the procedure. A selective, sensitive, and rugged detection system can ease or reduce the sample preparation procedures in a method, but not improve recoveries. Unfortunately, a highly sophisticated detection system cannot improve upon poor sample preparation procedures, nor can the achievement of very accurate and precise results by a laboratory extend beyond the scope of what the samples collected statistically represent. Therefore, the analytical strategy actually begins with devising an adequate statistically representative sample collection scheme, proper sample handling protocols, and appropriate QA/QC guidelines to meet the goals of the analysis. The USDA Pesticide Data Program serves as an example what is required to plan and implement a monitoring program to meet specified needs.[21]

Sample preparation consists of homogenization, extraction, and cleanup steps. In the case of multiclass, multiresidue pesticide analysis, different approaches can have substantially different sample preparation procedures, but employ the same determinative steps. Some detection methods may permit fewer sample preparation steps, but in some cases the quality of the results or ruggedness of the method suffers when short cuts are attempted. The manner in which sample preparation steps overcome the selectivity vs. polarity range conundrum inherent to multiclass, multiresidue analysis is often the most pivotal facet in the overall approach.

2.1 Homogenization and Sample Size

The choice of sample size and homogenization step begins the analytical strategy in the laboratory. However, sample collection, transport, and storage begin the overall process and as much care must be taken in these steps as any other. In applications that require the most care in the analysis, samples should be stored frozen, generally at the temperature of dry ice sublimation (−78.5 °C), or at −40 or −20 °C in freezers. For water samples, which may be too large to store in most laboratories, extraction is often performed as soon as possible after collection, and the concentrated extracts are stored. In many pesticide monitoring applications, even extremely large samples are extremely small in comparison with the commodity, environmental area, or other unit that the sample is meant to represent. It is often better to take several replicate samples of a manageable size, depending on the situation, rather than a larger sample that may be difficult to homogenize. The degree of variability of the sample type is determined by taking samples from different locations at the same time and/or samples at the same location over the course of time.[55]

Sample sizes in environmental applications generally range from very small (<1 g in particle phase samples) to very large (e.g. 400 m^3) in air analysis. For water, sample size is typically 1–4 L, but smaller or larger samples are sometimes adequate or necessary in certain applications. Soil samples range from ca. 3 to 100 g but, unlike many food samples, homogenization and subsampling procedures with large samples are not generally performed. Replicate samples from the monitoring area to be assessed are usually analyzed instead to improve the accuracy of the overall results.

In fresh food commodity applications, the FDA recommends taking samples of at least 20 lb. (9.1 kg) for comminution using an appropriate chopper.[1] However, many food sampling programs commonly take smaller sample sizes. In some cases, the variability of the individual items of the commodity is a goal of the study which involves the analysis of many individual items. Furthermore, the distribution of the pesticides within a single item may be desired, and appropriate samples (exposed surfaces, inner tissues, different sides, etc.) may be taken.

For extraction, current approaches do not conveniently extract solid samples sizes greater than 100 g, nor would larger sample sizes be desirable in most applications. Hence, subsampling of the larger composite sample is generally needed prior to extraction, and it is very important to homogenize the composite sample as well as possible. Miniaturization of the subsample size taken for analysis generally leads to a more cost-effective and convenient approach, and smaller amounts of potentially interfering matrix co-extractives have to be contended with or removed. In general, the smallest sample size should be taken that adequately represents what is intended and allows an adequate LOD. Increasing the sample size does not decrease the LOD if matrix co-extractives are the limiting source of noise in the analysis.

Simple precautions taken during the homogenization step can lead to great benefits in the steps that follow. Ideally, the food samples are comminuted in the frozen state to improve the quality and ease of homogenization, and to decrease pesticide losses.[56] Certain volatile (e.g. dichlorvos) and unstable pesticides (e.g. dithiocarbamates) are completely or partially lost during homogenization at room temperature.[57] The addition of dry ice is a common

approach to maintain cold temperatures and it also acts to introduce a dispersant which improves the homogenization process.[32] Other options are to perform the homogenization in a cold environment or to precool the mixing surfaces and work quickly. Otherwise, a special cryogenic mill may be used, but these devices are generally more applicable to small sample sizes.[58] The quality of the chopper and the use of an appropriate sample size in relation to the capacity of the chopper volume are also important factors in achieving the most homogeneous samples.[59] Even if all precautions are taken, certain matrix types and pesticides of interest may give more variable results than others. For example, Hemingway et al. found that cypermethrin homogenized in cabbage gave more reproducible results than in apple.[60]

2.2 Extraction

The extraction procedure begins the process to separate the analytes from the matrix and present the material in a form that can be more easily analyzed. Extraction strategies in multiclass, multiresidue analysis may be designed to (1) employ exhaustive extraction steps to achieve the desired wide range of analytes and rely on more postextraction cleanup steps to improve selectivity or (2) divide the analytes into different classes and utilize several selective extractions to cover the overall polarity range. Most laboratories opt for the former means to reduce effort in extraction, often at the expense of more effort in cleanup prior to analysis. However, cleanup steps can often achieve a higher degree of selectivity than most extraction steps because extraction frequently requires stronger measures to overcome analyte–matrix interactions and to reach small pores in the matrix. This reduces the degree of analyte/matrix selectivity that can be achieved in the extraction procedure.

The choice of solvent generally determines the selectivity of the extraction. With the introduction of instrumental techniques that control pressure and/or temperature of the solvent during extraction, a new way of extraction is emerging. The overall approach may be termed PFE, which consists of SFE,[61–64] microwave-assisted extraction (MAE),[65–67] and pressurized liquid extraction (PLE),[68–70] which is also referred by names such as accelerated solvent extraction (ASE™), pressurized solvent extraction (PSE), and enhanced solvent extraction (ESE). Of course, the extraction concept is the same independent of these approaches, but the use of these techniques to affect the dielectric constant, viscosity, and other properties of solvents can provide benefits in achieving the desired analyte solubilities, extraction kinetics, solvent-to-sample ratios, and a higher degree of selectivity. These techniques can also be useful to obtain more stringent conditions to help overcome matrix–analyte interactions.

Traditionally, liquid solvents at room temperature and pressure are used in the extraction of pesticide residues in solid samples. Table 7 provides some of the properties of typical solvents that are commonly used in the analytical laboratory for pesticide analysis. The important properties of the solvents in analytical applications include polarity (as estimated by the dielectric constant, ε), boiling point, density, miscibility with other solvents, viscosity, safety, and cost. The combination of these solvents at room temperature and pressure can provide a reasonable degree of control in the desired properties, but this ability is small when compared with the possibilities of adding the dimensions of pressure and temperature to the equation for the same solvents.

Pressure and temperature control also permits the inclusion of unconventional solvents, such as carbon dioxide and other substances which are gases at room temperature and pressure. A pressurized fluid that becomes a gas after extraction saves the trouble of performing time-consuming and wasteful solvent evaporation steps prior to analysis. Many instrumental techniques reduce labor and variability through automation. Furthermore, sample size reduction and a higher degree of selectivity in the extraction can reduce or eliminate the cleanup steps

Table 7 Properties of common solvents used in pesticide residue analysis

Solvent	Dielectric constant, ε	Polarity index	Viscosity ($mN\,s\,m^{-2}$)	Boiling point (°C)	Solubility in water (% w/w)
Water	78.5	9.0	1.00	100.0	–
Acetonitrile	37.5	5.8	0.37	81.6	100
Acetone	20.7	5.1	0.32	56.2	100
Methanol	32.6	5.1	0.60	64.6	100
Ethanol	24.3	5.2	1.20	78.4	100
Ethyl acetate	6.0	4.4	0.45	77.2	8.7
Diethyl ether	4.3	2.8	0.24	34.6	6.9
Dichloromethane	9.1	3.1	0.44	40.7	1.6
Toluene	2.4	2.4	0.52	110.8	0.05
Cyclohexane	2.0	0.2	0.98	80.7	0.01
Hexane	1.9	0.0	0.32	69.0	0.001

of the extract. The use of less solvent per fixed sample size by controlling pressure, temperature, and/or addition of gaseous co-solvents can also ease post extraction procedures (e.g. solvent evaporation and water removal in GC applications).

Despite the advantages of SFE, PLE, and MAE in some respects, traditional liquid-based methods at room temperature and pressure have advantages of their own. Traditional extraction methods are easy and do not require the added expense of purchasing and maintaining instrumentation. Fewer parameters to control and known expectations based on accumulated knowledge makes traditional method development less complicated. Liquids often serve as a good medium to homogenize samples and often limit analyte degradation and volatilization. In aqueous systems, the use of salts, acids, and bases often has a strong effect in extraction and partitioning. Unfortunately, the inherently wide polarity range of analytes in multiclass, MRMs handicaps techniques that permit a higher degree of selectivity. The optimal goal in any extraction is to match the polarity range of the analytes to be extracted, and not to exceed it.

At the present time, liquid-based extraction at room temperature and pressure remains the most common approach to extraction of pesticide residues. In the case of foods, a 2:1 liquid solvent-to-sample ratio is typical, and a blending device is employed in extraction. For environmental solid samples, Soxhlet extraction, sonication, and extended shaking with solvents are commonly used, and higher solvent-to-sample ratios are more common. Prior to the 1990s, water samples were more frequently extracted with liquid–liquid extraction (LLE) using an immiscible solvent, such as dichloromethane, but SPE has become the prevalent approach for water now. However, LLE can be adapted to use smaller volumes of organic solvents and increase convenience.[71]

The most common solvents used for extraction in multiclass, multiresidue analysis are acetone, acetonitrile, ethyl acetate, and methanol. For high-moisture samples, the water in the sample incorporates with miscible extraction solvents and helps to improve recoveries of many pesticides.[52] In the case of ethyl acetate (or dichloromethane and hexane), wet samples are frequently mixed with a drying agent, such as sodium sulfate, to remove water. In SFE, a similar procedure using diatomaceous earth or salt desiccants for wet samples is followed to prevent adverse effects of water[60,63,72] (supercritical CO_2 is only slightly miscible with water).

Water is considered the first choice as the extraction solvent for safety, cost, and environmental reasons, but water is not very useful by itself in typical multiclass, multiresidue applications. The less polar analytes are not extracted well with water, even at relatively high temperatures, but a host of problematic water-soluble matrix components often make cleanup more difficult.[1] Concentration steps are usually needed prior to analysis, and evaporation of water is very slow and relatively volatile pesticides are lost at conditions needed to evaporate water, even during lyophilization.[73,74] Also, many pesticides degrade more rapidly in water than in other solvents, and several other pesticides will either precipitate or otherwise interact with the glassware rather than remain in the water. It is possible to decrease the polarity of water by increasing the temperature and pressure, but then degradation is increased and polarity advantages of water are lost.

In extracts that contain water, however, the water should be concentrated or removed before analysis using conventional GC techniques (water is often not a problem in LC methods). Water can be separated from the mixture by exposing the solution to a drying agent,[75] addition of salt,[76] freezing-out the water phase,[77] and/or liquid–liquid partitioning with water-immiscible solvent(s). The organic phase is then usually concentrated by evaporation, which is why low-boiling solvents are desired to reduce the time of the extract concentration step. SPE is also utilized to separate the solutes from an aqueous solution. An advantage of SPE is that it concentrates the analytes as they partition out of the aqueous solution on to the solid sorbent. Thus, the concentration step after SPE is shortened or eliminated. Some polar analytes may break through SPE sorbents if the use of excessive aqueous volumes is attempted, but the problematic pesticides tend to be the same ones that only partially partition into the organic phase in LLE.[78]

The use of ethyl acetate as the extraction solvent avoids the water removal and partitioning steps, but ethyl acetate tends to be a less selective (or more exhaustive) extraction solvent than solvents that are completely miscible with water. Thus, ethyl acetate methods commonly require a solvent-intensive GPC step to remove co-extractives, even in the case of nonfatty matrices.[44] Less cleanup is usually needed for methods that use acetone and acetonitrile.[1,52] Acetonitrile is particularly useful in the case of fatty foods because fats have a lower solubility in acetonitrile than several other solvents.[79]

2.2.1 Solid-phase Microextraction

A novel approach using sorbents in relatively selective extractions is solid-phase microextraction (SPME).[80] Figure 5 shows a drawing of an SPME fiber. The key advantage of SPME is the simplicity of operation; all that is required is sequentially to place a fiber into a liquid or gaseous sample and then into a chromatographic injector. SPME works by coating a small fiber with a liquid polymer or solid phase and exposing this coated fiber to the sample. The analytes (and other chemicals)

Figure 5 Diagram of an SPME fiber. [Reprinted with permission from Pawliszyn.[80]]

partition into the coating phase and, after a certain time, the SPME fiber is desorbed (thermally or with solvents) into a GC or HPLC system.[80] Liquid samples are nearly always water in SPME because pesticide analytes tend to remain in organic solvents rather than partition into the fiber (and the coating may be stripped off the fiber in strong solvents). Even in the case of aqueous samples, many pesticides do not generally partition completely into the fiber, and salts are typically added to "salt-out" the pesticides and speed the partitioning process.

Important factors to control in SPME (with fixed fiber parameters) include exposure times, temperature, volumes, and stirring (if necessary). The exposure time may be short (5 min) in some applications in which the analytes quickly partition into the sorbent, or longer times (>1 h) may be needed in an attempt to decrease the LOD and increase the range of analytes. Quantitation can be performed from fundamental thermodynamic equations if all parameters are known and the system is at equilibrium. This is also true if the kinetics of the system are well known, but it is easier and more common to quantify results empirically as in other approaches with the use of calibration standards. Matrix components can greatly affect partitioning and lead to inaccurate quantitation,[81] but the method of standard additions or use of standards in matrix may help overcome this problem.

In multiclass, multiresidue applications, SPME can be too selective and not possess a sufficiently wide polarity range to extract the targeted analytes. At the same time, SPME may not be selective enough because it may extract too many matrix interferents. At this time, automated SPME systems and a few different fiber coatings that cover different ranges in polarity are commercially available. SPME can be very useful in applications of relatively clean air and water matrices for a reasonable number of pesticides, but direct extraction of complex samples is often problematic with SPME. To reduce problems of nonvolatile matrix components in liquid samples, the fiber may be placed in the headspace of the liquid. The amount of pesticide analyte extracted will not be altered, but it may take an exceedingly long time for the equilibration process between the liquid, headspace, and fiber coating phases. Overly small sample volumes can also be a disadvantage in SPME, and consequently the LOD may also be too high in SPME for some applications. In the future, the use of a coated capillary, as in a GC column, rather than a coated rod as in SPME, will permit larger volumes and shorter analysis times by being able to flow the sample through the capillary.[82]

Owing the frequently less than 100% partitioning of analytes into the fiber, the recovery concept of extraction is not necessarily an appropriate indicator in SPME.[83] However, recovery has traditionally been an indicator of accuracy in a method. Therefore, SPME may only be used in limited quantitative applications for pesticide residues, but it may become a prominent screening approach owing to its ease of use and potentially fast operation.[84] SPME can also be very useful in determining properties of pesticides such as Henry's law constants and in process monitoring systems.[85]

2.2.2 Extraction of Gaseous Samples

Analytes are extracted from gases by precipitation under cold conditions (e.g. cryofocusing), adsorbed by a solid (e.g. SPE), or absorbed into a liquid (e.g. bubbling into a liquid). SPME (a liquid absorption or solid adsorption approach, depending on the fiber coating) can be useful in the extraction of small volumes of gases or in air screening applications, but traditional air sampling approaches remain prevalent in environmental air studies. The use of polyurethane foam (PUF) for large-volume air sampling is an effective approach for a variety of airborne pesticides.[13,86,87] Other common solid-phase adsorbents include Tenax®, carbon, silica-based sorbents, and polymers.[88] The combination of low temperature with adsorption or absorption extraction methods can be used to increase extraction efficiencies.

2.3 Cleanup

The separation of analytes from undesirable matrix components, or "cleanup" of sample extracts, can be accomplished through liquid–liquid partitioning, liquid–solid partitioning, size-exclusion chromatography (SEC) or GPC, dialysis, distillation, centrifugation, filtration, precipitation, immunoaffinity, or other techniques that take

advantage of differences in the physicochemical properties of the analytes and the interferents. Owing to the way in which analysts choose to compartmentalize the overall multiresidue, multiclass strategy, different laboratories that use the same extraction methods may diverge during cleanup for different pesticide groups.

2.3.1 Liquid–Liquid Partitioning

Liquid–liquid partitioning has been an effective cleanup technique for over a century, and is still commonly used today. However, its disadvantages include the typical use of large volumes of potentially hazardous solvents, the necessity for concentration steps afterwards, the generation of hazardous waste, labor-intensive and/or time-consuming procedures, potential occurrence of emulsions, the need for a laboratory hood and storage space, added external source of potential sample contamination, and the dishwashing requirements of the many pieces of glassware. The traditional wet chemistry methods are slowly being replaced by newer methods that are more easily automated, take less labor, space, and time, and use less solvent and glassware. Despite the encroachment of newer cleanup approaches, however, liquid–liquid partitioning will remain a viable approach.

Dichloromethane and ethyl acetate are particularly useful solvents for the cleanup of acid–base pesticides in aqueous extracts. Changing the pH of the aqueous phase can help either to separate ionic pesticides from neutral compounds or to separate neutral pesticides from ionic compounds.[25] The use of chlorinated solvents, such as dichloromethane, has become a concern among many laboratories for waste disposal and safety reasons, but its immiscibility with water, ease of evaporation, solubilizing power, and greater density than water (hence it settles as the lower phase in a separating funnel) make dichloromethane a difficult solvent to dismiss.

Liquid–liquid partitioning can help remove fats from water and/or acetonitrile solutions with hexane or immiscible ethers.[25,89] One of the drawbacks for removing lipids with liquid–liquid partitioning approaches in multiclass, MRMs, however, is that lipophilic pesticides also tend to partition into the same phase as the lipids. A partitioning factor, or *P* value, can be used to correct for the known percentages of affected pesticides that partition with the fats under predetermined conditions.[90] However, this can lead to higher detection limits (owing to the analyte losses) and greater margins of error. Also, methods should achieve pesticide recoveries >70% to meet most QA criteria.

2.3.2 Gel Permeation Chromatography

The development of GPC, also known as SEC, in the 1970s caused the use of liquid–liquid and liquid–solid partitioning to diminish.[91] GPC achieves fewer losses of pesticides when separating fats and other large molecules by taking advantage of the molecular size differences of the larger chemicals from the smaller pesticides. Because many pesticides tend to have relatively similar molecular sizes, they can generally be collected in a single fraction. Another advantage is that the GPC column can be re-used many times and is easily automated, unlike typical uses of adsorbent columns. Unfortunately, many matrix co-extractives of similar molecular size as the pesticides are not separated in GPC, and other cleanup techniques may still be required afterwards. Practical disadvantages of GPC include the very large volumes of potentially hazardous solvents involved, the generation of waste, the need for post-GPC concentration steps, and the costs associated with purchase and maintenance of instrumentation and columns.[27] In recent years, new gel materials, more benign solvent combinations, and miniaturized columns have improved practical aspects of GPC, and it remains the most common means to remove high- and very low-molecular-weight components from food and environmental samples.[92]

2.3.3 Distillation

Another way to remove fats and other relatively nonvolatile materials is sweep codistillation (SCD).[93] Essentially, SCD can be likened to preparative-scale GC in which the relatively volatile pesticides are separated from nonvolatile components. Nitrogen gas is generally the mobile phase and silanized glass beads or other materials may be used as the stationary phase. SCD was commercially developed in the 1960s, but owing to variability of results with the approach, few scientists continued to use the technique.

More advanced instruments were developed in the 1980s which regenerated interest in the approach.[85] Thermally labile pesticides may be lost at the temperatures involved (~250 °C) and separate cleanup may still be required in some applications. In the analysis of OCs in fatty matrices, SCD has been shown to provide equally valid results as GPC and Florisil adsorption. However, with the use of current commercial instrumentation, SCD gave a 10-fold higher sample throughput and 40-fold lower solvent consumption than the other two approaches.[94]

2.3.4 Solid-phase Extraction

The most common and diverse approach to cleanup (and extraction of water samples) in pesticide residue analysis is SPE.[95–97] For several decades, liquid–solid partitioning has been an option for analytical chemists to separate components from a solution, but prior to the introduction of commercial SPE cartridges in the 1970s, liquid–solid

partitioning was performed using columns prepared by the analyst in the laboratory. The choice of sorbents for cleanup at that time were essentially limited to normal-phase applications with alumina, Florisil, silica, and charcoal. The poor reproducibility of the sorbents from batch to batch, their need for activation/deactivation, and the manual column preparation procedures involved led to variable results.

The advent and growth of HPLC in the late 1960s and 1970s led to more choices and better reproducibility of stationary phases. Reversed-phase applications with C_8 and C_{18} stationary phases and the commercial introduction of premade disposable cartridges initially made SPE a useful technique for the extraction and cleanup of aqueous samples and extracts. Over the last 20 years, improvements and diversifications in SPE formats, sorbent types, and apparatus have made SPE a widely used approach for a variety of applications, including multiclass, multiresidue analysis of pesticides.

SPE cartridges or disks can be likened to very low-resolution HPLC columns in that similar stationary and mobile phases are used. However, HPLC is not always helpful in determining conditions for SPE, and vice versa. Typical particle sizes in SPE are 40 μm, and the plastic cartridges are generally packed with 0.1–1 g of sorbent in wide tubes, whereas higher density packing of 5-μm stationary phase particles in narrower columns is currently prevalent in HPLC. Larger LC columns and typical injection volumes > 1 mL can be very useful for the cleanup of extracts in semipreparative LC.[23,25,98] With automated systems, SPE can be likened to semipreparative LC because the procedures and materials can be similar. The greater separation power of semipreparative LC, however, provides higher potential for better selectivity by collecting heart-cut fractions for later analysis or direct analysis in coupled analytical systems.

The choice of reversed-phase, normal-phase, and ion-exchange media in SPE is very diverse, and Table 8 lists some of the more popular SPE applications for cleanup of multiple pesticides. The modes of operation involve all options of either retaining, or not retaining, the analytes and/or matrix interferences through the selection of appropriate sorbents and solvents. SPE formats can be cartridges or membrane extraction disks of various sizes designed for single- or bi-directional flow. Recently, SPE has even been commercialized in disposable pipet tips for convenient miniaturized applications.

Table 8 Common SPE sorbents used in multiclass, multiresidue analysis of pesticides

Normal phase	Reversed phase	Ion exchange
GCB	GCB	SAX
Alumina (acid, base, neutral)	ODS (C_{18})	PSA
Silica	Polymer (DVB, other)	Aminopropyl (NH_2)
Florisil	Cyanopropyl (CN)	SCX

GCB, graphitized carbon black; DVB, divinylbenzene; SAX, strong anion exchange; PSA, primary/secondary amine; SCX, strong cation exchange.

The introduction of GCB and polymer-based sorbents, such as DVB, has led to modifications of some multiclass, MRMs for pesticides in water, soils, and foods.[99,100] Carbon has been known as an excellent liquid–solid partitioning sorbent for many years, but carbon was notorious among chemists owing to the great number of charcoal types, sources, and irreproducibility. The advantages of certain polymer-based sorbents in reversed-phase applications over silica-based sorbents include higher possible flow rates, wider pesticide polarity range, wider pH range, and allowance of the cartridge to go dry without losses. This is useful in applications, because water can be removed from the extract by drying the cartridge with flowing gas prior to elution of the analytes with the chosen solvent(s).

The choice of sorbent–solvent combination in SPE for cleanup of extracts is much like choosing the extraction solvent for certain pesticide(s) in a particular matrix. A great deal of experience with SPE and knowledge about the chromatographic behavior of the analytes and matrix co-extractives can save much effort in method development using SPE. However, trial and error is the more common approach to method development using SPE because unpredictable results and/or subtle differences may occur between different stationary–mobile phase combinations. Also, in multiclass, multiresidue applications, the need to maintain a wide polarity range of analytes does not allow the analyst to achieve the best degree of selectivity for the analyte as is possible in SPE (unless the analyst chooses to divide the extract into a series of separate cleanup procedures).

This polarity range dilemma can lead to unconventional SPE methods. For example, the use of a carbon or alumina (traditionally normal-phase sorbents) with acetonitrile (a solvent more common in the reversed-phase format) may separate interferences from analytes reasonably well in multiclass, multiresidue applications.[100] Also, stationary phases used in ion-exchange approaches, which have the strongest interactions in water, are used with nonaqueous mobile phases in multiclass, multiresidue procedures.[51]

The use of liquid–solid partitioning with charcoal, silica, Florisil and/or alumina is also possible to aid in the removal of lipids, but semipolar pesticides require large elution volumes and many relatively polar pesticides are completely retained by these adsorbing phases. The elution volumes and recoveries of different pesticides

from different columns and mobile phases are outlined in PAM I.[1] The recoveries of a large number of pesticides using the ''Luke'' and other methods tested by the FDA are also listed in PAM I.

2.3.5 *Automation*

Off-line SPE approaches are generally conducted manually in batches of 8–12 using SPE vacuum manifolds. Laboratories that conduct routine analysis have begun to use automated approaches in general, and SPE is no exception. A major advantage of SPE is that it can be automated and conveniently combined with exaction and/or analysis in a single instrumental arrangement.[101] The use of on-line, or coupled, LC approaches (including SPE) permits automation of analyses to reduce labor and typically increase sample throughput.

In SFE, it is common to collect and concentrate the extracts on a solid-phase trap, and a higher degree of selectivity can be achieved by using a sorbent used in SPE applications, such as C_{18}, as the trapping material in SFE rather than an inert surface or solvent.[102] In pesticide and other analytical applications of SFE, it is often preferable to use an SPE sorbent to attain higher trapping efficiencies, lower solvent consumption, and greater selectivity. By eluting the analytes with a certain volume of appropriate solvent(s), a simple and convenient SFE/SPE procedure can be conducted. PLE instruments also may permit the automatic combination of extraction and cleanup. GPC has also been combined with SFE,[103] but automation and coupling of liquid–liquid partitioning methods are uncommon.

The approach to coupling techniques may be taken a step further by linking the SPE step with an analytical instrument.[104] The introduction of the extract into a GC or HPLC instrument immediately after SPE is possible, but a small concentration step is more commonly performed in the attempt to lower the LOD. Direct coupling of GPC to the analytical instrument is very rare in pesticide residue studies because large solvent volumes must usually be evaporated after GPC, and in the case of reversed-phase HPLC the types of solvents used are not typically amenable.

2.3.6 *Matrix Solid-phase Dispersion*

Another way to combine SPE with the extraction process is to utilize matrix solid-phase dispersion (MSPD).[105] In MSPD, the sample is mixed with a solid-phase material which separates matrix interferents from the pesticide analytes during extraction. Thus, cleanup is performed at the same time as the extraction.

A form of MSPD is nearly always conducted in SFE and PLE to disperse the sample, absorb water, and/or retain unwanted matrix components. A relatively inert sorbent, such as diatomaceous earth, is used for sample dispersion and water absorption, but Florisil, alumina, silica, or other sorbents may be used to retain matrix components. Conversely, the choice of sorbent–solvent combination and extraction conditions may be designed to retain the analytes and remove the interferents. This technique, dubbed inverse extraction, is followed with a second set of extraction conditions to extract the analytes after the interferents have been removed.

MSPD has been evaluated in pesticide applications,[106] but drawbacks include the small sample size involved ($\sim$0.5 g) and the high cost of sorbents, especially if the sample size is increased. MSPD in multiclass, multiresidue analysis of pesticides at most uses a 4 : 1 sample-to-sorbent ratio.[107] The sorbents are generally the most expensive material cost in multiclass, multiresidue approaches that involve SPE.

3 ANALYTICAL SEPARATIONS AND DETECTION

Any approach applicable to the analysis of organic molecules (and a few inorganics) may be useful in the analysis of pesticides, but MRMs (and even single analyte methods) nearly always require an analytical separation step prior to the detection of the different analytes. Certain screening techniques may not involve a separation step, but positive findings would then usually require a determinative method to quantify and identify the pesticide(s).[108] Techniques that involve optical spectroscopy[109] or electrochemistry[110] may provide a degree of selectivity, but such detection methods are rarely used in residue methods except as detection after chromatographic separations.[111]

At this time, nearly all analytical methods utilize GC or HPLC as the separation step, but other column chromatographic techniques and CE are also reasonable options for conducting separations. Planar or thin-layer chromatography (TLC) may be acceptable in some applications, but currently TLC is typically used as an analytical approach only when the analyst places a higher priority on sample throughput than on achieving the type of higher quality results possible with more modern methods. However, TLC can be very useful in screening applications owing to its potential for high sample throughput and ability to provide better separation than several other screening approaches.[112] Fast GC or flash GC, in which the GC conditions are optimized for speed, is another chromatographic option,[113] but the this type of approach has not been utilized in routine applications.

The development of supercritical fluid chromatography (SFC) and experimentation with mobile phases consisting of dense gases, supercritical fluids, and/or

liquids at high temperatures and pressure has led some analytical chemists to think in terms of ''unified chromatography''.[114] Fundamentally, there are no stationary phase boundaries between GC, HPLC, and SFC, and the mobile phases are actually a continuum of fluids. Just as pressure and temperature control have added new dimensions in extraction processes, the control of pressure and temperature in chromatography coupled with the diversity of mobile and stationary phase options may lead to extraordinary possibilities in separations. For example, SFC has been demonstrated to separate an exceptionally wide polarity range of pesticides using a single set of conditions.[115] Pesticides that are currently analyzed by either GC or HPLC may be determined with a single unified chromatographic system. At this time, the lack of rugged injection and sensitive analyte detection processes has been the limiting factor in pesticide residue applications in this type of approach.

For detection, MS is rapidly becoming the method of choice for multiclass, multiresidue analysis owing to its many advantages, recent improvements in technology, and availability of cost-effective commercial instrumentation. Detection systems in general are continually being improved and, in combination with the improvements in chromatographic instruments and techniques, exceptionally low LODs are possible for pesticide residues.

3.1 Gas Chromatography

GC, also sometimes referred to as gas–liquid chromatography (GLC), is the most common method for the analytical separation of pesticides in multiclass, MRMs. The possible number of theoretical plates in separations and the variety and capabilities of the detectors that can be coupled to GC usually make it the first choice for analysis. Some laboratories decide to limit the types of analyses conducted by using GC for nearly all analyses. For example, certain pesticides may be included in a multiresidue GC method despite the fact that HPLC may provide better results, such as in the case of thiabendazole.[9]

3.1.1 Derivatization

The analysis of thermally labile pesticides is not possible using GC methods unless the analytes are converted into a more volatile and stable form. Analysis of the analyte in its natural state is the preferred approach in any method, and derivatization leads to extra procedural steps and other potential complicating factors. However, until recent advances in LC/MS, chemical derivatization for GC analysis was essentially the only option in the case of thermally labile pesticides that did not give high absorbance or fluorescence signals. At this time LC/MS continues to become more sensitive, more rugged, and less expensive, but chemical derivatization remains a common approach for targeted thermally labile pesticides using GC analysis.

If derivatization is performed in multiresidue, multiclass strategies, a portion of the original extract is usually separated from the fraction that will be used in the analysis of the larger number of pesticides. The extracts may need separate cleanup steps, but it is sometimes possible to recombine the different extract fractions for analysis with the same GC method.[116] Common derivatization procedures for GC methods involve the alkylation of acids which may also serve to add functional groups that achieve highly sensitive detection with the chosen detector. Other examples include the use of pentafluorobenzyl bromide to link with carbendazim (degradation product of benomyl and thiophanate-methyl),[117] among other single-class pesticide analysis schemes.[118,119]

One problem with derivatization is the possible lack of selectivity in the reaction which can make a host of other derivatized compounds. In single analyte methods, this is not usually a problem, but in multiresidue separations, the other derivatized compounds are more likely to interfere with detection of other analytes. Highly resolved separations and/or universally selective detection methods, such as MS or AED, may overcome this problem, but it is more common to follow single-analyte methods when performing derivatization.

3.1.2 Gas Chromatography Separations

The selection of GC conditions for the analysis of pesticides mostly depends on the targeted pesticides and chosen detector(s). A variety of sources are available for relative retention indices of pesticides on different stationary phases and conditions.[1,27,120] The choice of the column may not make a significant difference in the final quantitation of most pesticides,[9] but relatively polar pesticides often give better peak shapes using relatively polar stationary phases, whereas nonpolar pesticides can give good peak shapes in a variety of columns. The most common GC stationary phases in pesticide analysis consist of dimethylpolysiloxane or methylpolysiloxane with 5–50% phenyl, cyanopropyl, or cyanopropylphenyl. The use of packed GC columns has virtually been universally replaced with the use of capillary columns, which may be narrow-bore (0.25 mm i.d.), wide-bore (0.32 mm i.d.) or mega-bore (0.53 mm), or of other sizes depending on the application. Capillary columns narrower than 0.25 mm i.d. are rarely used in food or environmental multiresidue applications, and guard columns (also known as retention gaps) are often useful in the analysis of complex extracts.

Injection of 1–3 μL of extracts is typical using split/splitless techniques, but on-column injection has

advantages for some pesticides. Larger injection volumes (0.01–1 mL) are now possible with some current GC injection devices, but large-volume and/or on-column/cold injection methods in GC typically require more column maintenance than split/splitless volume techniques. Recent advances in GC instruments in addition to large-volume injection consist of exceptionally fast separations, improved columns, electronic pressure control, retention time locking, and other capabilities. These topics are discussed in section 55 of this Encylopedia.

3.1.3 Matrix Enhancement Effect

An important issue in the multiresidue analysis of pesticide residues in GC, particularly for polar OPs, is the ''matrix enhancement effect''.[121,122] This effect occurs owing to polar functional groups on the pesticide analytes interacting with silanol, metal ions, and other active sites in the surfaces of GC systems (mainly from glass in the injection liner). In the presence of matrix co-extractives which tend to fill the active sites, the matrix enhancement effect results in an increased analyte injection efficiency (and consequently a higher signal) for certain pesticides in the presence of matrix than in solvent solutions which contain no matrix. Thus, if pesticide solutions only in solvent are used for calibration standards, the recoveries of matrix spikes and concentrations of the affected pesticides in sample extracts are systematically overestimated. For low-level spikes of affected pesticides, it is not unusual to observe enhancements of >150%. Table 9 provides results that show which pesticides are (and are not) affected by the matrix enhancement effect. These results are averaged from a number of food analyses over the course of time using different GC detectors as part of the Swedish MRM.[44] Owing to the nature of multiclass, multiresidue analysis, it is difficult to completely overcome this effect for polar OPs.[123] The use of deuterated internal standards, on-column or high-flow injection,[124] coating the injection liners with column phase, or method of standard additions can overcome or compensate for the matrix enhancement effect, but the most practical and common way to avoid the problem is to use calibration standards in blank matrix extracts.[27,34,44,122] Blank extracts are usually obtained from real samples in the monitoring program that have been shown to be free of residues, but blank field samples, which are often included in some studies anyway, may also be used as material for matrix-matched calibration standards.

3.1.4 Selective Detectors

For detection, the flame ionization detector (FID) and photoionization detector (PID) are rarely used in pesticide residue applications, in part, owing to the lack of selectivity, but the use of traditional selective detectors is a very common approach to multiresidue analysis of pesticides.[1] The use of a halogen-selective detector [ECD, electrolytic conductivity detector (ELCD), or halogen-specific detector (XSD™)] in conjunction with a phosphorus- [flame photometric detector (FPD), pulsed flame photometric detector (PFPD), NPD], sulfur- [FPD, PFPD, sulfur chemiluminescence detector], and/or nitrogen-selective detector (NPD, PFPD) is a common approach to cover a wide range of pesticides and to reduce sample cleanup. The AED is another element-selective detector, but it is useful for a number of elements simultaneously.[125,126] The PFPD is also useful for the selective detection of 28 elements (up to two simultaneously), and can provide lower LODs at a lower cost than an AED.[127]

Some multiclass, multiresidue schemes use up to five detectors in separate GC analyses which are selective for halogens, nitrogen, phosphorus, sulfur, and other elements, plus MS for confirmation. Thus, each sample extract requires five GC injections, plus HPLC methods, to analyze and identify the wide range of pesticides targeted for analysis. Some analysts choose to split the flow of a GC separation to two detectors which minimizes the number of injections, but this approach also reduces the amount of analyte that reaches the detector and complicates separations by using the same column for all analytes.[128]

3.1.5 Gas Chromatography/Mass Spectrometry

The most widely regarded approach to accomplish the analysis of as many pesticides as possible in as few steps as possible is to use MS detection.[129–132] MS is considered a universally selective detection method because it detects all compounds independent of elemental composition and further separates the signal into mass spectral scans to provide a high degree of selectivity. Unlike gas chromatography/atomic emission detection (GC/AED), gas chromatography/mass spectrometry (GC/MS) may provide acceptable confirmation of the identity of analytes without the need for further information. This reduces the need to reinject a sample into a separate GC system for pesticide confirmation. Through the use of selected ion monitoring (SIM), efficient ion-trap or quadrupole devices, and/or tandem mass spectrometry (MS/MS), modern GC/MS instruments provide LODs similar to or lower than those with selective detectors, depending on the analytes, methods, and detectors.

MS detection does not necessarily require as highly resolved GC separations as in the case of selective detectors because the likelihood of an overlapping mass spectral peak among pesticides with the same retention time is less than the likelihood of an overlapping peak from

Table 9 Average matrix effect (% recovery) for pesticides in food commodities using the Swedish method (from A. Andersson, H. Pålsheden, B. Arén, 'Matrix Effects in Pesticide Multiresidue Analysis', 1st European Pesticide Residue Workshop, Alkmaar, The Netherlands, June 10–12, 1996, P-055)

the same element. Unfortunately, this advantage cannot always be optimized because in SIM and current gas chromatography/tandem mass spectrometry (GC/MS/MS) methods, the ability to detect two analytes at once increases the LOD of each analyte. Overlapping full-scan mass spectra can also pose problems with confirmation, so baseline resolution of as many pesticides as possible is still desirable. Low-bleed capillary columns are typically used in GC/MS systems to reduce background noise, but until recently, only nonpolar phases had low-bleed properties. The commercial introduction of relatively polar low-bleed phases has improved the capability to achieve good separations and peak shapes for the relatively polar pesticides at the same conditions for nonpolar pesticides.

Another reason that it is difficult in practice to achieve the lowest LOD possible for more than about 100 pesticides in a single injection by MS and MS/MS is that some pesticides provide lower LODs when using positive ion chemical ionization (PCI) while others are better detected in electron impact ionization (EI) or negative ion chemical ionization (NCI) modes.[27] It is not uncommon for analysts to use a series of injections in GC/MS to best cover the large number of pesticides (>300) possible with the approach.[129,133] Sequential EI and PCI modes used in the same run is possible with some instruments, but this approach is seldom used.

The precision of GC/MS for analysis of pesticide residues generally varies from 5 to 20% RSD, which is similar to that in approaches using other GC detectors.[9] Quantitation with modern GC/MS instruments suitably meet the needs of most quantitative applications. However, some chemists have decided to use MS only for applications involving the determination of unknowns, confirmation of pesticide identities, and/or rapid screening.[134]

3.1.6 Pesticide Identification

Confirmation criteria in pesticide residue analysis are a subject of debate, depending on the application, but it is generally recognized that human judgment is required in the final decision. Criteria to consider in MS include: (1) proper GC retention time; (2) three ions of correct mass/charge (m/z) ratios; (3) adequate signal-to-noise ratios; and (4) absence of similar signal in blank samples (to indicate no contamination or carryover).[135] The definitions of ''proper'' ''correct'' and ''adequate'' are based on the need and importance of the result. In any case, some pesticides do not provide three ions in their spectra, or the ion ratios for some spectra may be more variable than deemed acceptable if strict definitions are used. Other factors are sometimes taken into account, such as chromatographic peak shape, sample history, and/or analyst experience. In these difficult cases, information from other analyses, perhaps using other ionization modes in MS or even infrared spectroscopy,[111] are sometimes performed to gather more evidence. The combination of an element-selective detector and MS can provide excellent information for determining the presence of an analyte, or just as important, eliminating the chance that a pesticide is present.[126] The added selectivity gained in the use of multiple mass spectrometry (MS^n) can also weigh heavily in confirmation of pesticide identity despite the possible lack of three ions of defined ratios.[132,133] Some older methods of confirmation, such as the use of two different stationary phases in GC, are no longer acceptable in many cases, especially if the results will be used for regulatory purposes.

3.1.7 Direct Sample Introduction

Conventional wisdom maintains that elimination of cleanup steps in an analysis reduces the quantitative capabilities and/or ruggedness of the analysis. The effects of matrix and/or lack of ruggedness are often the biggest limitation of using the modern sensitive and selective detectors in GC analysis of complex extracts. The detectors may be capable of discriminating low-level analytes from potentially high-background interferents, but the GC injector can become contaminated with nonvolatile components after only a few injections unless cleanup is performed. A recent advance, direct sample introduction or ''dirty sample'' injection (DSI), has addressed these factors.[136,137]

DSI improves the ruggedness of the approach because nonvolatile components that can contaminate GC columns and MS sources remain in the disposable sample vials used for injection. Figure 6 shows a drawing of a DSI device inside a GC injection port. In DSI, samples are extracted by the means available, and up to 30 μL of the liquid extracts are placed in a disposable vial. Essentially, DSI operates by thermal desorption of sample extracts from the vial placed in the injection port into the GC column. This is not unlike SPME, which also does not contaminate the GC system (because nonvolatile components remain in the fiber coating during injection), but extraction methods in DSI can provide a wider analyte polarity range than SPME. This is because DSI operates solely on analyte volatility whereas SPME depends on partitioning ratios into the fiber coating. Furthermore, the expensive, reusable SPME fiber remains contaminated with nonvolatile materials after injection whereas the inexpensive microvial in DSI is disposable.

The DSI approach for complex extracts requires the use of selective detection to discriminate the pesticide analytes from the other semivolatile matrix components in the extract, but the use of selective detectors, such as PFPD,[137] and also MS[136] and MS^n,[138] can meet this challenge. The quantitative aspects of DSI

Figure 6 Diagram of a DSI device. [Reprinted with permission from A. Amirav, S. Dagan, *Eur. Mass Spectrom.*, **3**, 105–111 (1997).]

with GC/MS/MS has been demonstrated for 23 diverse pesticides in fruits and vegetables.[138] Recoveries were near 100% (ca. 10% RSD) with the approach, and the LODs were $<1\ \text{ng g}^{-1}$ for the pesticides.

3.2 High-performance Liquid Chromatography

The common need to achieve separation of so many analytes in multiclass, multiresidue applications tends to preclude HPLC as the primary means of analytical separations. However, HPLC is often an integral part of an overall analytical scheme in which the approach is used for the analysis of single classes of pesticides not amenable to GC.[1,27,53] Typically, reversed-phase high-performance liquid chromatography (RPHPLC) is employed for the thermally labile, semipolar and polar pesticides. Normal-phase HPLC is capable of separating nonpolar and semipolar pesticides,[139] but these types of pesticides are not typically thermally labile and the GC methods often give better separations and lower detection limits. Some laboratories may choose to derivatize thermally labile pesticides for an overall method relying on GC analysis,[140] but it is generally preferable to detect the analytes as they occur in the sample. Thus, HPLC is a common alternative to GC derivatization methods. Liška and Slobodník reviewed and compared the use of GC and LC methods for the analysis of polar pesticides in water.[141]

HPLC is a more rugged approach than GC owing to the continual rinsing of the system with liquid and simple means of liquid sample introduction. HPLC permits the injection of larger sample volumes (typically 25–250 μL) than GC (typically 1–3 μL), which also helps to improve the sensitivity of HPLC methods. Despite this aspect, LODs in GC methods with selective detectors may be lower than those in HPLC methods (depending on the analysis), despite the much larger HPLC injection volume. A disadvantage of HPLC is the potentially large amount of mobile phase solvent needed and waste generated. However, solvent recycling, newer and smaller packing phases, narrower columns, and slower flow rates are reducing this potential drawback. The articles on HPLC (section 59 of this Encyclopedia) should be consulted for a discussion of these and other aspects of HPLC.

3.2.1 Detectors

HPLC detectors are not as varied as GC detectors. Common HPLC detectors used in pesticides residue analysis include ultraviolet/visible (UV/VIS), fluorescence, and MS detectors, whereas electrochemical detectors are less commonly used. Currently, single-wavelength UV/VIS absorbance is a common approach to detection in HPLC, but this approach is well noted for its general lack of selectivity, especially at low wavelengths, and inability to detect analytes that do not contain chromophores. The diode-array detector (DAD), also called photodiode array (PDA), provides a higher degree of selectivity, but it is also limited to the detection of analytes with chromophores and is usually associated with higher LODs than single-wavelength detectors. Fluorescence is a much more selective and sensitive option for HPLC detection, but few pesticides fluoresce strongly enough to warrant a separate method for their detection, especially in multiclass, MRMs.[109] A beneficial feature of spectrophotometry and spectrofluorimetry, however, is their nondestructive nature, which enables them to be combined in series with themselves[142] and/or other detection methods (such as MS) to increase the overall selectivity.

3.2.2 Post-column Derivatization

Even though certain thermally labile and nonvolatile pesticides may be amenable to separation in HPLC, their detection can be difficult with traditional detectors if they do not provide a sufficient absorbance, fluorescence, or electrochemical signal. Derivatization of the analyte to improve detection (with any detector) is sometimes the only option to meet desired the LOD. If the pesticide

analyte can be derivatized in a rapid reaction, then postcolumn derivatization can be a useful method for detection in HPLC. Chemical derivatization steps during the sample preparation are an option prior to HPLC analysis, and have the added benefit of permitting longer reaction times, but traditionally GC would be used if HPLC postcolumn derivatization is not feasible. Postcolumn derivatization eases the sample preparation process because separate derivatization steps are not needed, and the pesticides have already been separated by the analytical HPLC column. Because relatively few other reactive compounds are likely to be present at the analyte retention times, the selectivity of the overall approach is further increased.

Fluorescence detection is the most common postcolumn derivatization approach owing to the high sensitivity and selectivity of the detector. A common approach in the postcolumn derivatization process is the reaction of *o*-phthaldialdehyde with amines. Heat or ultraviolet (UV) radiation applied to a reaction bed or length of narrow tubing may be used to drive the reaction. Postcolumn derivatization fluorescence detection in HPLC is useful in the analysis of several amine-containing pesticides, such as carbamates, ureas, and certain organophosphates.[143] In particular, postcolumn derivatization fluorescence detection has become the standard approach for the analysis of *N*-methylcarbamate insecticides.[1,26,27,53,143]

3.2.3 Liquid Chromatography/Mass Spectrometry

Owing to the rapid pace of major advances in LC/MS, a number of reviews of LC/MS and its use in the analysis of pesticides has been published in recent years.[144–146] There has been a strong need for a universal and selective detector such as MS in LC (and other) applications since the advent of the technique. In the 1980s, moving belt, particle beam (PB), and thermospray (TSP) interfaces were used with limited success in the analysis of pesticides.[147] With the improvements and commercialization of liquid nebulization interfaces and atmospheric pressure ionization (API) for MS, the need for derivatization of thermally labile pesticides for GC or HPLC detection is expected to wane.[148] Applications of liquid chromatography/particle beam mass spectrometry (LC/PBMS) and liquid chromatography/thermospray mass spectrometry (LC/TSPMS) for pesticides have essentially been replaced with techniques using atmospheric pressure chemical ionization (APCI) and electrospray (ESP) ionization, also known as ionspray (ISP), techniques.[149] Modern LC/MS instruments capable of ESP and APCI modes, and that now fit on a benchtop, provide lower LODs, more facile and rugged operation, and lower costs than ever before. LC/MS instruments are still several times the price of a traditional system, but the identification and universal detection capabilities of MS (or MS^n) make it a powerful analytical tool.

Many of the same general advantages and disadvantages of GC/MS are prevalent in high-performance liquid chromatography/mass spectrometry (HPLC/MS), but a higher degree of complexity and more limitations are associated with HPLC/MS. Most notably, the current main ionization modes in LC/MS (ESP, APCI) can give very different ionization levels and responses for different pesticides.[150] This is further complicated by the choice of positive or negative ionization in each of the two ionization modes which leads to a choice of four possible LC/MS operating conditions (+/− ESP, +/− APCI), none of which can currently be interchanged during the course of a run. This further limits the utility of LC/MS for multiclass, multiresidue pesticide methods in a single run. Furthermore, the use of the soft ESI and APCI ionization techniques and easy formation of analyte–salt adducts mean that separate injections from the quantitation method may still be needed to conduct confirmation through collision-induced dissociation (CID) of the analytes. Also, owing to salt build-up in the interface, high concentrations of nonvolatile salts should not be added to the mobile phase in LC/MS, thereby diminishing the ability to optimize buffers and ion-pairing reagents which are helpful in some pesticide applications.[142] Also, lower flow rates are often used in LC/MS, particularly with ESP unless split flow or other precautions are taken, which often necessitates the use of more precise pumps and smaller columns than in traditional HPLC applications. However, this aspect may in fact be advantageous because narrow columns, smaller stationary phase packings, and low flow rates in HPLC separations may lead to improved LC/MS applications for pesticides.

3.2.4 Signal Suppression Effect

Another drawback in LC/MS is the signal suppression effect that is prevalent when an analyte co-elutes with a matrix component.[151] MS detection can isolate the analyte from the co-eluting peak through the proper choice of mass(es), but the quantitation can be significantly affected by a reduction in the ionization efficiency of the analyte prior to MS detection. Unlike the matrix enhancement effect in GC, which can lead to overestimation of the calculated concentration for affected pesticides, the signal suppression effect in LC/MS leads to lower resulting calculated concentrations. The methods of reduction or control of the effect may be possible through one or more of the following approaches: (1) further cleanup of the extracts; (2) alteration of the separation conditions; (3) utilization of a different ionization technique; (4) addition of deuterated internal standards; (5) use of the method of standard additions;

and (6) use of calibration standards in a blank matrix. Another approach is to correct results for recoveries, but this is not acceptable in many QA protocols, and the results are typically inaccurate when the effect is concentration dependent.

3.2.5 Liquid Chromatography/Tandem Mass Spectrometry

The use of liquid chromatography/tandem mass spectrometry (LC/MS/MS) (or MS^n) does not overcome the signal suppression effect in the presence of interferents, but it can be very useful in avoiding interfering masses and reducing the LOD when two peaks co-elute.[152] There are two types of instruments for MS/MS detection, either tandem quadrupole or ion-trap, that each have advantages and disadvantages with respect to each other. Triple-stage quadrupole MS instruments generally have better precision, ability to determine neutral losses (which is useful in making identifications), and higher mass resolution. The ion-trap instruments are generally smaller, cheaper, and provide MS^n capability. LC/MS/MS (or MS^n) is considered the state-of-the-art approach for many of the modern pesticides and their metabolites, and pesticide manufacturing companies have relied heavily on the use of the LC/MS approaches in the development and analysis of pesticides. As single-analyte methods are developed for pesticide registrations using LC/MS approaches, the application of these techniques in multiclass, MRMs is expected to increase.

3.3 Capillary Electrophoresis

CE is a technique developed in the early 1980s, but it has only recently made its way into pesticide residue applications.[153–156] A variety of formats and options for different types of applications are possible in CE, such as micellar electrokinetic chromatography (MEKC), isotachophoresis, capillary gel electrophoresis (CGE), and capillary electrochromatography (CEC), but biochemical and pharmaceutical applications, not pesticide residues, remain the major focus in studies that use CE.[157] The main problem with CE for residue analysis of small molecules has been the low sensitivity of detection in the narrow capillary used in the separation. With the development of extended detection path lengths and special optics, absorbance detection can give reasonably low detection limits with clean samples.[156] However, complex samples can be very difficult to analyze using CE/UV. CE coupled with laser-induced fluorescence detection can provide extraordinarily low LODs[158] but the analytes must be fluorescent with excitation peaks at common laser wavelengths for this approach to work. Derivatization of the analytes with appropriate fluorescent labels may be possible, as is done in biochemical applications, but pesticide analysis has not been such an important application to utilize such an approach.

As in HPLC, the coupling of MS detection with CE has provided an excellent opportunity for more selective analysis, but the much reduced flow rates, small injection volumes, limitations in the types of buffers used, and the need to maintain a large voltage potential along the capillary make CE/MS (capillary electrophoresis/mass spectrometry) more complicated than LC/MS.[155] Furthermore, 1000-fold lower injection volumes in CE lead to higher LODs in CE/MS than in LC/MS. Techniques such as stacking multiple CE injections can increase injection volumes to possibly overcome the sample injection volume limitation in CE.[153,156,157]

The main advantages of CE over HPLC relate to the greater number of theoretical plates, reduction in the use of hazardous solvents, lack of waste, utility in sample limited applications, and general capability for lower LODs with UV and fluorescence detectors (owing to increased resolution in separations and higher signal-to-noise ratio despite the smaller injection volume).[25] Unlike the laminar flow profile of chromatographic techniques, plug flow occurs in CE because flow originates along the capillary walls. This generally translates into sharper peaks in CE and better separations.

A common criticism of CE is the lower consistency of migration times for peaks than in HPLC or GC. The effects of matrix components and small differences in ionic strength and pH can have significant effects in the separation. The use of a migration time marker provides a consistent relative migration time that may be used to identify peaks of interest, especially in complex electropherograms.[25] As in HPLC, it is often difficult to separate a diverse range of pesticides in CE with the same set of conditions. Hence, CE applications are most likely to be limited to single-class MRMs.[154] CE is most useful for ionic pesticides, but neutral analytes are also possible targets using CEC and MEKC.[159]

3.4 Immunochemical Methods

Immunochemical techniques may be useful for fairly rapid and reasonably inexpensive techniques for selected pesticides, or perhaps a selected class of pesticides, but the application of immunochemistry in multiclass, MRMs is limited.[160–163] The advantages of the high selectivity, reasonable ease, and relatively low costs are lost when several antibodies are needed to increase the analytical range of the technique. As in nearly all approaches, the selectivity of immunochemical techniques decreases as the analytical range increases, and costs and complexity concomitantly increase. Furthermore, the results of immunoassays are often only semiquantitative, and

separate methods may be needed for quantitation and identification. Furthermore, immunochemical techniques are only useful in aqueous solutions, and pH, ionic strength, matrix components, temperature, and other factors can have large effects in the assays. However, some enzyme-linked immunosorbent assays (ELISAs) are satisfactorily quantitative, rugged, and capable of detecting very low levels (<1 ppb) of targeted pesticides. For example, commercial ELISAs for triazine (e.g. atrazine) and acetanilide (e.g. alachlor) herbicides have performed particularly well in environmental monitoring applications.

In ELISA, relating signal to the concentration is more complicated than traditional means because the calibration plot is inversely proportional and semilogarithmically correlated to the analyte concentration. Also, the signal in ELISA consists of the absorbance of a sample divided by the absorbance from blank sample(s). Furthermore, the analytical range for quantitation in ELISA is generally less than two orders of magnitude. For these reasons, ELISA is not especially useful for quantitative analysis, especially with complex extracts, but its capabilities can be useful in screening applications for individual pesticides. Cleanup of complex extracts has been performed prior to ELISA to improve reliability and quantitation, but in this case it is often less expensive and more reliable to use a traditional method in the laboratory.[164]

At this time, ELISA kits are commercially available for approximately 25 pesticides, but several other antibodies have been developed for other pesticides in noncommercial applications. Depending on the format, ELISA kits typically cost \$5–10 per assay, which is similar to the cost of materials in typical quantitative and confirmatory multiclass, MRMs (Table 6). ELISA tests are often performed in batches and can take from 15 to 120 min, depending on the incubation times for the competitive reaction and enzymatic color change. A batch can consist of 96 samples in the microtiter plate format, but usually fewer samples are analyzed owing to the need for replicates. In the commercial magnetic bead format, replicates are less necessary owing to lower variability, and up to 60 samples may be analyzed in a batch. In some cases, portable ELISA kits can be applied in the field using tube formats with detection by eye or with tube photometers.

Interestingly, many of the disadvantages with ELISA in residue analysis are also advantages, and vice versa, depending on the application. For example, the high selectivity of detection in ELISA is a disadvantage in multiresidue applications. The costs and labor of ELISA increase significantly if more than one kit is to be used to detect a number of pesticides. Also, the use of ELISA can be considered slow and tedious compared with SPME, DSI, or MS screening applications, but it is generally much easier and faster than single-analyte methods. However, the semiquantitative and nonconfirmatory nature of ELISA can potentially lead to a high rate of false positives and false negatives. Even if the results are reliable, a determinative and/or confirmatory method is often required in the case of a positive response.

The capabilities of immunochemical methods are highly dependent on the antibody. A rugged antibody of high selectivity can provide exceptional results for the targeted analytes in complex extracts that may even contain a small percentage of organic solvents in the aqueous solutions. In other cases, the antibodies may have poor stability and be affected strongly by pH, salt content, temperature, and matrix components. Some antibodies are specific to a single antigen, whereas others are selective to a chemical moiety, and still others can interact rather nonselectively with a variety of compounds. By altering incubation times and antibody-to-sample-to-enzyme–antigen ratios, the sensitivity of analysis can be tailored to achieve very low, or not as low, detection limits.

Investigations of immunochemical or biochemical formats that are potentially faster, more quantitative, easier to perform, less expensive, more rugged, and suitable for a wider range of pesticides than ELISA are being conducted. These approaches involve enzymes, biosensing, flow injection, optical fibers, molecular imprinting, and other methods.[165–167] Biosensing methods of analysis that take advantage of modes of action of different pesticides, e.g. cholinesterase inhibition, can be very effective but, unfortunately, current cholinesterase-based detection kits for OPs and carbamates are not sensitive enough for most monitoring applications.[168] Sensitive, specific, rapid, and reliable screening assays based on immunochemical or biosensing concepts are commercially available and widely used in clinical and veterinary testing applications. However, the analysis of pesticides has not warranted such attention from manufacturers, mainly owing to the need for multiclass, multiresidue results rather than those for specific analytes. Unless these type of techniques for pesticide residues become commercially available, they will only rarely be used because the process to prepare the biosensing or immunological materials is often expensive, time-consuming, and complicated. Screening methods are often desired to increase the number of monitored samples, but fast and accurate analytical methods other than biosensing or immunological techniques are more likely to be developed for a wide range of pesticides to meet the analytical goals.

4 CONCLUSIONS

Owing to the introduction of a number of sophisticated technologies and instruments, tremendous improvements

Table 10 CAS numbers, usage, classes, and solubilities in water [from Hornsby et al.[31]] for many pesticides

Common name	CAS No.	Use[a]	Class	Solubility (mg L^{-1})

[a] D = defoliant; F = fungicide; H = herbicide; I = insecticide/acaricide.

in the ability to analyze multiple pesticides for multiple classes in a variety of sample matrices have occurred in recent years. A growing number of techniques are available to the analytical chemist, and many strategies are possible to meet the purpose of analyses. In general, the use of the fewest analytical steps that provides reliable results in a rugged approach serves as the best overall approach to determining pesticide residues in food, environmental, and other types of samples. An inherent difficulty in multiclass, multiresidue analysis is that as the range of analytes increases, the overall selectivity of the sample preparation decreases. Therefore, trade-offs and compromises must often be made in obtaining high recoveries of a wide range of analytes while minimizing time, effort, and cost of the procedure(s).

Ultimately, these fundamental and practical aspects may limit the ability of the strategy to meet the needs of the analysis. As this article describes, a host of strategies are available to the chemist, but practical concerns in the laboratory, such as time, budgets, available instruments, and personnel, limit the amount of effort and resources that can be devoted to the analysis. A clearly superior, efficient and all-encompassing strategy has yet to be devised, which has made method development in multiclass, multiresidue analysis of pesticides an active area of study. The number of different pesticides and sample types leads to unique challenges in the determination of multiclass, multiresidue pesticides that few other areas of analysis match.

Finally, for reference, a list of a wide range of pesticides, with CAS numbers, uses, classes and solubilities in water are given in Table 10.

ABBREVIATIONS AND ACRONYMS

AED	Atomic Emission Detection
AOAC®	Association of Official Analytical Chemists
APCI	Atmospheric Pressure Chemical Ionization
API	Atmospheric Pressure Ionization
ASE™	Accelerated Solvent Extraction
CDFA	California Department of Food and Agriculture
CE	Capillary Electrophoresis
CEC	Capillary Electrochromatography
CE/MS	Capillary Electrophoresis/Mass Spectrometry
CGE	Capillary Gel Electrophoresis
CID	Collision-induced Dissociation
DAD	Diode-array Detector
DSI	Direct Sample Introduction or ''dirty sample'' injection
DVB	Divinylbenzene
ECD	Electron-capture Detector
EDTA	Ethylenediaminetetraacetic Acid
EI	Electron Impact Ionization
ELCD	Electrolytic Conductivity Detector
ELISA	Enzyme-linked Immunosorbent Assay
EPA	US Environmental Protection Agency
ESE	Enhanced Solvent Extraction
ESP	Electrospray
ETU	Ethylenethiourea
EU	European Union
FDA	US Food and Drug Administration
FID	Flame Ionization Detector
FPD	Flame Photometric Detector
GC	Gas Chromatography
GC/AED	Gas Chromatography/Atomic Emission Detection
GCB	Graphitized Carbon Black
GC/MS	Gas Chromatography/Mass Spectrometry
GC/MS/MS	Gas Chromatography/Tandem Mass Spectrometry
GLC	Gas–Liquid Chromatography
GLP	Good Laboratory Practices
GPC	Gel Permeation Chromatography
HPLC	High-performance Liquid Chromatography
HPLC/MS	High-performance Liquid Chromatography/Mass Spectrometry
ISO	International Standards Organization
ISP	Ionspray
ITD	Ion-trap Detector
LC	Liquid Chromatography
LC/MS	Liquid Chromatography/Mass Spectrometry
LC/MS/MS	Liquid Chromatography/Tandem Mass Spectrometry
LC/PBMS	Liquid Chromatography/Particle Beam Mass Spectrometry
LC/TSPMS	Liquid Chromatography/Thermospray Mass Spectrometry
LLE	Liquid–Liquid Extraction
LOD	Limits of Detection
LOQ	Limit of Quantitation
MAE	Microwave-assisted Extraction
MEKC	Micellar Electrokinetic Chromatography
MRL	Maximum Residue Limit
MRM	Multiresidue Method
MS	Mass Spectrometry
MS^n	Multiple Mass Spectrometry
MS/MS	Tandem Mass Spectrometry
MSPD	Matrix Solid-phase Dispersion
NASS	National Agricultural Statistics Service

NCI	Negative Ion Chemical Ionization
NPD	Nitrogen–Phosphorus Detector
OC	Organochlorine Pesticide
ODS	Octadecylsilane
OP	Organophosphorus Insecticide
PAM I	Pesticide Analytical Manual, Vol. I
PAM II	Pesticide Analytical Manual, Vol. II
PB	Particle Beam
PBMS	Performance-based Measurement Systems
PCI	Positive Ion Chemical Ionization
PDA	Photodiode Array
PFE	Pressurized Fluid Extraction
PFPD	Pulsed Flame Photometric Detector
PID	Photoionization Detector
PLE	Pressurized Liquid Extraction
PSA	Primary/Secondary Amine
PSE	Pressurized Solvent Extraction
PUF	Polyurethane Foam
QA	Quality Assurance
QC	Quality Control
QMA	Quaternary Methylamine
RPHPLC	Reversed-phase High-performance Liquid Chromatography
RSD	Relative Standard Deviation
SAX	Strong Anion Exchange
SCD	Sweep Codistillation
SCX	Strong Cation Exchange
SEC	Size-exclusion Chromatography
SFC	Supercritical Fluid Chromatography
SFE	Supercritical Fluid Extraction
SIM	Selected Ion Monitoring
SOP	Standard Operating Procedure
SPE	Solid-phase Extraction
SPME	Solid-phase Microextraction
TLC	Thin-layer Chromatography
TSP	Thermospray
USDA	US Department of Agriculture
UV	Ultraviolet
UV/VIS	Ultraviolet/Visible
XSD™	Halogen-specific Detector

Organochlorine, Pyrethrin and Pyrethroid Insecticides: Single Class, Multiresidue Analysis of

Alfonso Di Muccio
Istituto Superiore di Sanità, Rome, Italy

1 Introduction **2**
1.1 Dichlorodiphenyltrichloroethane and Related Compounds 2
1.2 Hexachlorocyclohexanes 2
1.3 Chlorocyclodienes 5
1.4 Camphechlor 5
1.5 Other Relevant Organochlorinated Compounds 6
1.6 Pyrethrins and Pyrethroid Insecticides 6
1.7 Analytical Methods 6
2 Sample Preparation **6**
3 Extraction **9**
3.1 Nonfatty Samples 9

Organochlorine (OC) pesticides is a general term for a broad class of compounds including some well-known compounds such as dichlorodiphenyltrichloroethane (DDT), lindane, dieldrin, endrin, heptachlor epoxide (HEPO), endosulfan, and chlordane. OC pesticides are the first class of compounds introduced in agricultural and civil uses to counteract noxious insects and insect-borne diseases. In general they are lipophilic compounds with noticeable chemical and environmental stability. Although most OC pesticides have been progressively restricted and then banned in the 1970s in most industrialized countries, a widespread environmental pollution has resulted from their use in agriculture and civil uses.

Pyrethrins are natural insecticidal compounds found in the extract of pyrethrum flowers. Also, a number of pesticides have been synthesized that share the biologically relevant chemical moiety with the pyrethrins and are referred to as pyrethroids (PYR). These compounds possess equal or better biological activity and better chemical stability that allow their use in agriculture, husbandry, and civil applications. Both OC and PYR pesticides can occur in fruits and vegetables as well as in food of animal origin and environment. The levels can be different as a result of direct application or indirect contamination. Such different matrices and levels of contamination require different analytical approaches and resources.

A review is presented of the array of the analytical techniques most frequently applied for the extraction, cleanup and identification/determination. Extraction techniques include solvent extraction, supercritical fluid extraction (SFE), solid-phase extraction (SPE), and solid-phase microextraction (SPME). Solvent extraction is carried out in different ways depending on the type of matrix (fatty and nonfatty samples, soil, sediments, and water), such as Soxhlet, liquid–liquid extraction (LLE), pressurized liquid extraction (PLE), and matrix solid-phase dispersion (MSPD).

Different cleanup techniques are presented that can be applied to fatty and nonfatty samples. They include liquid–liquid partitioning (LLP), size-exclusion chromatography (SEC), sweep codistillation and assisted distillation, column adsorption chromatography, chromatography on SPE cartridges, high-performance liquid chromatography (HPLC), thin-layer chromatography (TLC) and degradative cleanup. The techniques are presented as modular steps that can be arranged in different ways to cope with cleanup requirements posed by different sample composition and different selectivity/sensitivity of the identification/determinative techniques. The performances of the cleanup steps are discussed in terms of matrix removal

and amount of sample that can be handled. Also the possibilities of linking different steps and the chance for automation of the cleanup process are indicated. Some environmental pollutants, such as polychlorinated biphenyl (PCB), have similar analytical behavior to some OC pesticides and can occur in the same environmental matrices. Some cleanup steps useful for the group separation of PCB and OC pesticides are presented.

The techniques for identification and determination include gas chromatography (GC) with selective detectors, HPLC, and their combination with mass spectrometry (MS). The importance of the combination of responses from different analytical techniques to obtain reliable identification at trace levels is underlined.

1 INTRODUCTION

Pesticides are chemicals intended to combat unwanted or noxious organisms in a variety of matrices in different fields of application such as agriculture, husbandry, civil, and industrial premises. Pesticides belong to a wide range of chemical classes and are divided into categories of organisms they counteract (insecticides for insects, acaricides for mites, nematocides for nematodes, fungicides for fungi, and herbicides for weeds).

The modern history of pesticides dates back to World War II when for the first time the insecticidal properties of DDT were recognized. DDT was first introduced on a large scale to fight fleas, lice, flies, and mosquitoes and reduce the spread of insect-borne diseases such as typhus (body lice), malaria, and yellow fever (mosquitoes) and plague (fleas).[1]

The first synthetic pesticides belong to the broad class of OC pesticides which includes the chloro diphenyl aliphatics (DDT, dichlorodiphenyldichloroethane (DDD), methoxychlor), the hexachlorocyclohexanes (HCHs), chlorocyclodienes (heptachlor, aldrin, chlordane, dieldrin, endrin, and mirex).[2,3] Table 1 gives chemical formulas of the cited OC pesticides.

Pesticides as well as other chemicals released into the environment tend to distribute into different compartments and their distance from the site of application depends on the chemico-physical properties and chemical stability of the pesticide and the environmental conditions. Pesticide degradation processes involve biotic (vegetable and animal metabolism, microorganism and enzymes) and abiotic (oxidation, hydrolysis, breakdown by heat and ultraviolet (UV) light) transformations. OC pesticides are generally recognized as highly stable lipophilic compounds. Thus, they have a tendency for bioaccumulation in fatty tissues of animals along the food chain.

1.1 Dichlorodiphenyltrichloroethane and Related Compounds

DDT belongs to the class of diphenyl aliphatics, which consists of an aliphatic chain with two phenyl rings attached. DDT was produced as a technical material comprising the *p*,*p*′-DDT and *o*,*p*′-DDT isomers and the related compounds *p*,*p*′-DDD (TDE), *o*,*p*′-DDD (TDE), *p*,*p*′-DDE (dichlorodiphenyldichloroethylene) and *o*,*p*′-DDE. A typical sample of technical DDT comprised 77.1% *p*,*p*′-DDT, 14.9% *o*,*p*′-DDT, 0.3% *p*,*p*′-DDD, 0.1% *o*,*p*′-DDD, 4.0% *p*,*p*′-DDE, 0.1% *o*,*p*′-DDE, with the remaining 3.5% being unidentified compounds. Besides being present in the technical product, some of these compounds are also metabolites of DDT. Two main pathways of DDT metabolism exist in mammals, i.e. dehydrochlorination to DDE and stepwise conversion to DDA (di(*p*-chlorophenyl)acetic acid) via DDD. DDE and DDD are also formed in insects, soil, and to a lesser extent in vegetables. In many industrialized countries DDT has been progressively restricted and then banned in the 1970s. However, it is still used in some countries to control malaria. Therefore, from an analytical perspective, the determination of the complex of isomers and metabolites is important at residue level.[4] Related pesticides include TDE (DDD) (which has not been used to a great extent), methoxychlor and dicofol.

Methoxychlor is an insecticide. Owing to the presence of two methoxy groups at *para* positions on the phenyl ring, methoxychlor is less environmentally stable than DDT and it is degraded via *O*-dealkylation and dehydrochlorination. Thus, methoxychlor has a poor tendency to bioaccumulation.

Dicofol is a nonsystemic acaricide used to control phytophagus mites. It is degraded in plants and animals to dichlorobenzophenone (DCBP).[5] Its synthesis and degradative pathways have some steps in common with DDT and its metabolites.[6]

1.2 Hexachlorocyclohexanes

HCH is made by chlorination of benzene, which results in the formation of five isomers differing in the spatial position of chlorine atoms and named using the Greek letters α, β, γ, δ, and ε. Only the γ-isomer (lindane) has insecticidal activity and is present at about 14–15% in the technical material, which also typically contains 65–70% α-HCH, 7–10% β-HCH, and ca. 10% of δ- and ε-isomers. Technical material was initially used for insect control, but after recognizing its undesirable characteristics (musty odor and flavor), only lindane continues to be used for a limited type of application, such as seed treatment, in industrialized countries.[4] However, the other isomers are more persistent than lindane and

may still be found at residue levels in the environment and animal tissues.

1.3 Chlorocyclodienes

The main compounds in this class are chlordane, aldrin and dieldrin, heptachlor, endrin, mirex, α-endosulfan and β-endosulfan. They are persistent insecticides which may be used in some countries mostly in soil applications. Because of their persistence, the use of chlorocyclodienes on crops, except endosulfan, was restricted and/or banned between 1975 and 1980.

Technical endosulfan consists of a mixture of α- and β-isomers in the approximate ratio of 70:30 (w/w). Endosulfan is less persistent than the other chlorocyclodienes, and oxidizes into endosulfan sulfate. Dieldrin, besides being an insecticide per se, is the oxidation product of aldrin. Heptachlor and chlordane also oxidize into heptachlorepoxide and oxychlordane, respectively. Other compounds such as *trans*-nonachlor are present at residue level as byproducts of the synthesis of heptachlor, while hexachlorobutadiene is a common byproduct of the chlorination process. Chlordane has two isomers, α and γ, and is also present in technical heptachlor.[1–4]

1.4 Camphechlor

Camphechlor (toxaphene) is manufactured from the chlorination of camphene and consists of more than

177 polychlorinated derivatives, most of them being isomeric C_{17}, C_{18}, and C_{19} bornanes. Toxaphene is an insecticide mainly used in cotton fields and for the control of termites. Toxaphene is persistent in soil but is fairly easily metabolized by mammals and birds, and does not accumulate in body fat to such a great extent as do DDT, HCH, or chlorocyclodienes. Despite its low toxicity to mammals, insects, and birds, fishes are highly susceptible to toxaphene poisoning.[1–4]

These compounds as well as PCBs occur in the environment as complex mixtures at trace level and require special analytical methodologies which are not specifically dealt with in this article.[7]

1.5 Other Relevant Organochlorinated Compounds

Hexachlorobenzene (HCB) is actually a fungicide used in the past in the treatment of stored grains. It is highly lipophilic and is found ubiquitously in environmental fatty matrices.[4] It is also found as a contaminant of quintozene (pentachloronitrobenzene), a fungicide used in soil treatments.[4]

PCBs are materials used mostly in the past years in industrial applications such as dielectrics, heat exchangers, and brake and hydraulic fluids. Accidental release and/or inadequate waste disposal has lead to widespread environmental pollution. Because of their stability and lipophilicity they pose almost the same problems as OC insecticides and behave similarly in most analytical procedures.[3]

A number of other polychlorinated compounds are of concern in environmental pollution including polychloronaphthalenes, polychloroterphenyls,[4] polychlorodibenzodioxins and polychlorodibenzofurans.[4]

1.6 Pyrethrins and Pyrethroid Insecticides

With the development of pesticide chemistry other classes of insecticides have been introduced. These include organophosphates and carbamates that are generally much more acutely toxic to vertebrates than OCs insecticides. They are less chemically stable and persistent than OCs and do not give rise to environmental bioaccumulation.

Pyrethrins are insecticidally active compounds present in the extract of pyrethrum flowers. Pyrethrin extract contains six related compounds, but the analysis is focused on the main and more active compounds, pyrethrins I and II, which are present at about 33–35% each in the extract. Pyrethrins are normally used in formulations containing the synergist piperonyl butoxide, which is also of analytical interest. Pyrethrins have rapid knock-down activities on insects, but are not suitable for agricultural uses because of their instability in sunlight.

One of the last classes of insecticides introduced is PYR. In the course of several years a number of compounds have been synthesized that possess some of the characteristics of pyrethrins combined with sufficient environmental stability and residual activity for agricultural uses. Most PYR pesticides were first introduced on the market as a mixture of stereoisomers resulting from the synthesis. Individual enantiomers have different biological activity and are increasingly used in formulations. Also the degradation of the enantiomers is different in the environment and at residue level.[4]

Some of the above-mentioned compounds are shown in Table 2.[5]

Depending on the chemical structure, stability, chemicophysical properties, environmental conditions, and time and mode of application, pesticides used in agriculture and in civil applications or sanitary programs may give rise to residues in crops at harvesting and/or in different environmental matrices. In general terms, residues occur as high as a few milligrams per kilogram (ppm, parts per million) for pesticides used in agriculture, but indirect, long-lasting contamination by persistent compounds such as OC pesticides may be found ubiquitously at microgram per kilogram (ppb, parts per billion; 1 in 10^9), nanogram per kilogram (ppt, parts per trillion; 1 in 10^{12}), and femtogram per kilogram (ppq, parts per quadrillion; 1 in 10^{15}), levels.

1.7 Analytical Methods

It is obvious that analytical determinations at such widely different levels pose different difficulties. However, a tremendous number of publications have been devoted to the development of methods for pesticide residue analysis in foods and environmental matrices.

The determination of OC and PYR pesticides follows some common approaches applicable in general to the determination of trace amounts of organic compounds in complex matrices.[8–17]

2 SAMPLE PREPARATION

The analytical method is generally considered to begin with sample preparation. Sample preparation involves the isolation of the sample portions that are indicated in the definition of the legal limit, or maximum residue level (MRL), for foods, or the portion of the substrate for which the analysis is intended. Afterwards, this sample portion (*analytical sample*) is taken for analysis. The analytical sample is often larger than the amount strictly needed for the analysis from a technical point of view, but the larger size may be more convenient to work with or lead to a more representative sampling procedure. Otherwise,

a procedure should be applied to derive the *aliquot of analysis*, i.e. the portion of the sample brought to the extraction step. In order to have a representative aliquot, the laboratory/analytical sample should be thoroughly comminuted (chopped, or milled) and mixed to obtain an homogeneous material. If possible, the entire laboratory/analytical sample should be processed. If this is not possible, a reducing procedure such as quartering (division into quarters and taking opposite corners), is applied. When applying a quartering procedure to large

units, they should be divided according to their symmetry, taking into account that the distribution of pesticide residues may not be even.

The differences in the sample structure may also require different procedures and mechanical equipment to get a homogeneous analytical sample. Most biological samples are better comminuted while frozen. For this purpose, liquid nitrogen can be useful (e.g. cryogenic milling). The addition of dry ice keeps the sample frozen and increases the mechanical shredding. Comminution at low temperature is also recommended to avoid decomposition of heat-labile compounds. Lyophilization is sometimes used to remove the water from the samples in order to increase the aliquot taken for the analysis and/or to facilitate the extraction, but may give rise to losses by evaporation.

The action of chopping, cutting, blending, or milling machines should be evaluated with representative crops or goods to be analyzed in order to check the performance with samples of different texture and to assess the minimum size of the aliquot of analysis that can be still considered representative of the laboratory sample.[18] Homogenization is particularly important when using methods that require a small aliquot for analysis. The variance of the sample preparation adds to the variance of the analytical procedure and can contribute significantly to the overall quality (accuracy and precision) of the results.[19]

3 EXTRACTION

3.1 Nonfatty Samples

Extraction is the step aimed at separating the analytes from the insoluble part of the matrix and transferring them into a solvent amenable to the subsequent steps of the method. The use of different solvents and solvent mixtures has been reported, depending on the analytes and matrices. In multiresidue methods, the extraction solvent should extract polar and apolar analytes because it is of interest to extract as many analytes as possible. Increasing the polarity of the solvent improves the extraction of polar analytes, but generally increases the amount of coextractives.

For nonfatty samples (commonly those containing less than 2–5% fat), water-miscible solvents such as acetonitrile,[8,9,20,21] acetone,[22–29] ethanol,[30] and methanol,[31,32] or polar, partially water-miscible solvents such as ethyl acetate,[33–35] are among the most frequently used. Most methods require 2 mL solvent per gram of sample. Although acetonitrile is known to give cleaner (less waxes and fats) extracts than acetone it has some drawbacks such as higher toxicity, higher cost, high boiling point, and the formation of a two-phase system with water when fruits or vegetables with low water and/or high sugar content are analyzed.[36] Alternatively, acetone is less toxic and expensive, and has a lower boiling point. Methanol also has been less frequently used because of its toxicity, although it is indicated as a better extracting solvent for some categories of pesticides such as carbamates,[9] but does not work as well for nonpolar analytes.

Low-moisture foods, such as grains, are better extracted with solvent mixtures such as acetonitrile–water (65 : 35 v/v),[8,37] acetone–methanol (1 : 1 v/v),[38] or acetone–water (8 : 1 v/v).[39] Water helps to swell the dried material, thus allowing a better penetration of the water-miscible solvent. Both water and methanol generally improve the extraction by reducing the adsorption of the analytes on insoluble material and container surface, but this is not necessarily the case for nonpolar compounds. The process of extraction is carried out by homogenizing a portion of the previously comminuted sample in high-speed blenders/homogenizers. The solvent is separated by filtration after the addition of filter aids, such as diatomaceous materials, or after centrifugation. In the extraction with ethyl acetate or other solvents immiscible with water, anhydrous sodium sulfate is added to remove the water.

3.2 Fatty Samples

Most methods for fatty foods have been developed for PYR, OC and organophosphorus (OP) pesticides due to the lipophilic nature of these pesticides. The most common approach entails thorough extraction of the fat to completely extract lipophilic pesticides. Therefore, extraction procedures for pesticides follow the classical methods for the determination of total fat content. For instance, animal tissues and dairy products are thoroughly mixed with anhydrous sodium sulfate to remove water and help disintegrate the tissues. Then the mixture is extracted with a Soxhlet apparatus with petroleum ether,[40] or *n*-hexane–acetone (59 : 41 v/v) mixture,[41] or *n*-hexane–dichloromethane (DCM) (4 : 1 v/v),[42] or blended at high speed.[43] The solvent is evaporated and the raw fatty extract is obtained after evaporation of the extracting solvent,[40,42] or after partition into *n*-hexane and evaporation.[43]

In some cases, an extraction step may not be needed. For example, butter fat is obtained from butter by melting and filtering to remove the solids. Fats and oils can be subjected directly to one of the cleanup steps.

Milk and dairy products are usually extracted with the total fat extraction approach using petroleum ether–diethyl ether (1 : 1 v/v), after the addition of denaturing agents such as potassium oxalate, which solubilizes the proteins, and methanol or ethanol, that avoids the formation of emulsions. Also human serum has been

extracted with petroleum ether–diethyl ether in the presence of methanol.[44] Extraction of total milk fat and lipophilic pesticides is also possible with a combination of apolar and polar solvents, such as *n*-hexane–acetone (50 : 50 v/v),[40,45] ethyl acetate–ethanol (95 : 9 v/v),[46] or ethyl acetate–acetone–methanol (2 : 4 : 4 by vol.),[47] or with acetone alone[48] or acetonitrile.[49]

Eggs have been extracted according to the total fat extraction approach by drying with anhydrous sodium sulfate and blending with a mixture of *n*-hexane–acetonitrile (2 : 1 v/v),[50] which has been proved to extract more fat than extraction with petroleum ether–diethyl ether.[8]

In a different approach, fatty tissues can be extracted with acetonitrile.[49,51] In this case, a selective extraction of pesticide residues including OC and PYR pesticides is accomplished. Pesticide residues are extracted efficiently while most of the fatty matrix is left, with great advantages in the subsequent cleanup process.

Also, for milk a selective extraction of pesticide residues is possible by mixing the milk with acetonitrile and ethanol and partitioning into *n*-hexane,[52] or by mixing with acetonitrile and passing the resulting solution through an SPE C_{18} cartridge (SPE with octadecyl-silica), which traps the OC pesticides.[49] In both cases OC pesticides are recovered efficiently accompanied by a substantially lower amount of fat than in the conventional total fat extraction approach. This amount of fat allows a small-scale cleanup with saving of solvents, adsorbents, and time.

The above-mentioned extraction processes are carried out by putting into intimate contact the sample and the solvent. Mechanical blenders/homogenizers are most commonly used, and ultrasound is often applied to this end. The extracting solvent is separated by centrifugation or by filtration through paper or glass fiber disks, often after the addition of filtration aids, usually diatomaceous earth. Not infrequently emulsions and/or jelly suspensions are formed that complicate the separation of the extracting solvent. Addition of small amounts of polar solvents or saline solution and centrifugation are often useful to overcome this problem.

3.3 Matrix Solid-phase Dispersion Extraction

In a different approach, MSPD (sometimes referred to as on-column extraction), the intimate contact between the sample and the solvent is realized by thoroughly mixing the finely divided sample with solid sorbents. Common sorbents used in MSPD include diatomaceous earth material (Celite, Extrelut, Hydromatrix), synthetic magnesium silicate (Florisil), or silica. The sample plus material mixture is packed in a column and eluted with the solvent under gravity at ambient temperature. This column extraction has been reported for vegetables mixed with Extrelut (10 g vegetable + 12 g Extrelut eluted with 100 mL DCM)[53,54] or Hydromatrix (25 g sample + 25 g Hydromatrix eluted with 250 mL ethyl acetate),[55] or Florisil (5 g vegetable + 8 g Florisil eluted with 70 mL DCM–acetone (9 : 1 v/v) or ethyl acetate).[56] In a similar application 5 g vegetable was mixed with 8 g Florisil and extracted on-column with 60 mL *n*-hexane–acetone (9 : 1 v/v).[57]

Milk and dairy products, and eggs, were mixed with silica gel (5 g sample + 15 g silica gel), while fish tissue was mixed with sodium sulfate and clean sand (1 g fish + 3 g sea-sand and 10 g sodium sulfate). In both cases, the sample mixture was loaded onto the top of a 10% water-deactivated silica gel column, and the bilayer column eluted overnight with 150 mL petroleum ether–DCM (80 : 20 v/v).[58,59] In these applications, the on-column extraction performs both the extraction and cleanup, because the extract is passed in-line through the silica gel adsorption column. In similar applications, OC pesticides can be extracted from fish tissue homogeneously mixed with C_{18} powder (0.5 g tissue + 2 g C_{18}). The mixture is put on the top of a small column of Florisil. The bilayer column is eluted with 8 mL acetonitrile.[60–62] The MSPD takes advantage of the sample shredding generated while grinding the sample with irregularly shaped solid particles, and lipid-retaining ability of a lipophilic support (C_{18}). Thus, the bilayer column carries out both a selective extraction and a cleanup step (Florisil) in a single process. MSPD uses mild conditions for extraction (ambient temperature and pressure) and has been found useful in avoiding the degradation of dicofol to DCBP during Soxhlet extraction of avian eggs.[63] Preferential flow and sample that has not been carefully mixed are the principal drawbacks that can result in poor recovery.

Also the selective extraction of OC, OP, and PYR pesticides from milk and milk powder can be carried out by loading a mixture of milk or reconstituted milk with acetonitrile and ethanol (5 mL of a mixture of 10 mL milk + 5 mL acetonitrile and 1 mL ethanol) into a cartridge filled with Hydromatrix. The OC, OP, PYR pesticides are selectively recovered from the material by eluting the cartridge with 20 mL *n*-hexane saturated with acetonitrile and ethanol. Milk fat is carried over to a limited extent (ca. 5 mg mL^{-1} of milk) compared to the nominal fat content (ca. 180 mg mL^{-1}) of the whole milk and the subsequent cleanup can be miniaturized to save solvents, reagents, and time.[64–66]

3.4 Soil and Sediments

OC pesticides are extracted from soil by shaking the sample overnight with *n*-hexane–acetone (1 : 1 v/v) (typically 10 g with 100 mL) after the addition of ammonium chloride solution.[8] Fenpropathrin and fluvalinate have

been extracted from soil mixed with charcoal (25 g soil + 0.5 g charcoal) by column extraction with 100 mL *n*-hexane–acetone (9 : 1 v/v).[67] Lower solvent/soil ratio (20 mL/10 g) with methanol and sonication for 15 min proved more efficient and rapid than the conventional shaking method or Soxhlet extraction in extracting some PYR pesticides from soil.[68] Sonication provides a more efficient contact between the solid and the solvent, but longer sonication caused a decrease in recovery, probably due to some degradation of the compounds. Sonication for 5 min and high solvent/soil ratio (150 + 100 mL/20 g) were found necessary in a multiresidue method for extracting 120 pesticides, including OC and PYR, from high organic matter soil.[69]

To improve the efficiency of the extraction, heat can be supplied by microwave energy. The principle involves heating both the solvent and the matrix by wave–matter interaction. The process is carried out in a special microwave oven (typical conditions: 10 g soil and 30 mL *n*-hexane–acetone (1 : 1 v/v) at 110 °C for 10 min). As a result both temperature and pressure are increased and there is a chance of degradation of sensitive compounds by exposure to high temperature and catalytic sites in the soil.[70–72]

3.5 Water

Water or wine is extracted by classical LLE in a separatory funnel by shaking it with an immiscible solvent such as DCM.[73,74] To increase the sensitivity and avoid concentration of the extracting solvent, OC and PYR pesticides can be extracted from water with a small volume of *n*-hexane (1 mL). After the extraction, the hexane layer is raised up to the bottle neck of the separatory funnel by raising the communicating vessel filled with deionized water.[75]

Water and water-diluted liquid samples can be passed through lipophilic SPE cartridges to extract OC and PYR pesticides. The most widely used sorbents are C_{18}, polystyrene–divinylbenzene (PS–DVB), and graphitized carbon.[76] A typical application includes extraction of 1 L of water,[77,78] or 50 mL of wine diluted with 200 mL of water,[79] both with a 500-mg C_{18} cartridge. Centrifuged human plasma (1 mL diluted with 3 mL water) was passed through a 100 mg C_{18} cartridge.[80]

Filter disks of polytetrafluoroethylene with C_{18} particles embedded have been used to speed up the extraction of large samples (about 20 min with a 47 mm diameter disk compared to about 1–2 h with a C_{18} cartridge, for a 1 L sample).[81,82] Automated SPE can be combined with large-volume GC introduction techniques for the automated extraction and determination of PYR pesticides in water.[76,83]

SPME is a solventless extraction technique in which the analytes are extracted directly from the aqueous samples onto a polymeric stationary phase that coats a fused silica fiber. The fiber is dipped into the aqueous sample under stirring (in certain applications the fiber is exposed to the headspace above the sample) allowing the adsorption of the analytes, according to their partition coefficient, into the polymeric phase. The analytes are thermally desorbed directly into a gas chromatograph by inserting the fiber into the hot injector. After a few minutes the fiber is withdrawn and reused for subsequent analysis. Different fiber coatings provide different adsorption properties for different compounds. The most commonly used fiber coating is poly(dimethylsiloxane), which is relatively nonpolar, and useful for nonpolar compounds such as OC pesticides. For more polar analytes a polyacrylate coating has been used. Fiber coating thickness is in the range 15–150 μm. Temperature and time of absorption and desorption have to be optimized in relation to the sample characteristics and analytes. The typical temperature for absorption is from ambient to 45 °C for 20–90 min, while the desorption temperature is in the range 250–260 °C for a few minutes. Elimination of solvents, easy automation, and the possibility of on-site sampling are among the advantages of SPME.[84–90] On-line solvent desorption into a liquid chromatographic column has been developed for compounds that require HPLC for analysis.[85]

3.6 Pressurized Liquid Extraction

PLE is a semiautomated technique in which extraction can be enhanced and speeded up, and solvent consumption reduced, by increasing temperature and pressure. As in MSPD, the sample is mixed and dispersed with macroporous materials such as Hydromatrix and/or anhydrous sodium sulfate. This acts to disperse the matrix, improve homogeneity, and ease flow of solvent through the sample. The mixture is loaded into a closed vessel through which the solvent is passed under increased temperature and pressure. The solvents are those normally used for conventional extraction procedures. The technique basically uses a static extraction step of 5 min at elevated temperature (50–200 °C) and pressure (7–20 MPa) that enhances solubilization and desorption of the analytes from the matrix, followed by a washing of the cell with fresh solvent for total recovery of the extracted analytes.[91] Dried materials such as soil are mixed with anhydrous sodium sulfate in about a 1 : 1 w/w ratio and extracted with *n*-hexane–acetone (1 : 1 v/v)[92] or DCM[93] for 5 min static extraction at 100 °C and 13.8 MPa under conditions similar to those of EPA Method 3545.[94] Other pesticides have been extracted from soil mixed with Hydromatrix (1 : 0.1 w/w) by acetonitrile under the same conditions.[95] PLE gives excellent recoveries in a short time and has been compared favorably with Soxhlet, sonication, microwave-assisted extraction (MAE) and

SFE.[71] Vegetable samples were mixed with Hydromatrix or Extrelut in a 1:1 w/w ratio and extracted with ethyl acetate at temperatures of 50–100 °C and a pressure of 143.8 MPa for 5 min. Typical sample sizes are 5–10 g mixed with inert material in a 11- or 22-mL vessel eluted with 20–40 mL. Lower temperature reduces the amount of water in the extract that has to be removed by anhydrous sodium sulfate. Furthermore, under increased temperature and pressure there is a chance of degradation as in MAE in a closed vessel. Instruments are commercially available under the trade names ASE, ESE, and PSE for processing multiple samples.

3.7 Supercritical Fluid Extraction

In SFE sample preparation is quite similar to that in PLE; the sample is extracted by passing a supercritical fluid (typically CO_2) through the cell. In some cases, a small amount of polar solvent modifiers (e.g. methanol, ethanol, or acetonitrile) is added to improve extraction, depending on the analytes and matrix. SFE is a relatively selective extraction technique which has been applied to the extraction of pesticide residues from vegetables, soils, and fatty tissues with a reduced removal of coextractives. However, expensive apparatus and selection of appropriate conditions are needed, and, in the case of fatty foods, further cleanup for OC pesticides is needed prior to determination. Typical sample sizes are 2–5 g in 10-mL vessels.

Fatty and nonfatty samples are mixed with Hydromatrix in a 1:1 to 1:2 w/w ratio to retain the water that would be extracted by supercritical CO_2.[96–99] Typical conditions are: 2 min static extraction followed by dynamic extraction at 20–32 MPa and 40–60 °C with CO_2 flow rates in the range 1.6–3 mL min^{-1} for six extraction vessel volumes. The extract is collected in a trap filled with chromatographic material such as C_{18},[97,98] alumina, Florisil or glass beads,[99] usually at ambient or subambient temperature. For lyophilized fish powder the trap was Florisil.[100] Inclusion of alumina in the extraction vessel served to reduce the extraction of fat from lyophilized fish. However, while PCBs were satisfactorily recovered, some degradation of DDT was observed.[101,102] A cartridge of chromatographic material such as silica gel, aminopropyl silica gel, or Florisil connected in-line downstream to the extraction vessel adequately separated PCBs from lipids when eluted with supercritical CO_2.[103] In another application to fatty samples, the extracted material is cleaned up by passing the supercritical fluid in-line through a preparative column of methyl silica (C-1) connected downstream to the extraction vessel.[104] A multivessel SFE instrument has been evaluated for the simultaneous extraction of up to six fatty samples.[105]

4 CLEANUP

Cleanup is the part of the analytical method aimed at selectively removing as much coextracted material as possible before the identification/determination step. The amount of coextracted material that needs to be removed is often dictated by the selectivity, sensitivity, and robustness of the determinative technique and by the concentrations at which the analytes are measured. Therefore, cleanup may consist of a single step or a combination of steps, some of which are essential and some of which can be omitted depending on the type of sample, extraction method, and the technique and instrumentation used for identification/determination. In some instances, the raw extract can be analyzed without cleanup. In any case, cleanup is a compromise involving efficiency, time, and cost. Although published methods report specific sequences of cleanup procedures (blocks), most cleanup steps can be arranged in desired sequences to separate particular types of chemicals, or deal with particular problems.

Simple operations can be used to link different cleanup blocks by tailoring the approach to most conveniently take into account the amount of coextracted material and type of solvent each block can accept. Solvent exchange, i.e. concentration to dryness and redissolution in a suitable solvent, is the most common operation between different steps of the analytical method.

Cleanup includes an array of chemical separations aimed at removing unwanted coextractives by taking advantage of physico-chemical differences in polarity, dissociation constants, volatility, molecular size, chemical stability, solubility in different solvents, and other factors.

4.1 Liquid–Liquid Partitioning

4.1.1 Nonfatty Samples

When fruits, vegetables, and other nonfatty samples are extracted with water-miscible solvents such as acetone, acetonitrile, and methanol the usual subsequent step in the approach involves the dilution of the extract with saline solution and the extraction of pesticide residues from the diluted raw extract with an immiscible solvent or solvent mixture by shaking in a separatory funnel. Hydrophilic coextractives remain preferentially in the watery phase, while nonpolar and semipolar pesticide residues partition into a solvent that is more easily evaporated and amenable to the subsequent cleanup steps. The more polar the extracting solvent, the wider the range of the analytes that can be recovered, but the amount of the coextractives generally increases. For recovery of low to medium polarity analytes, such as OC and PYR pesticides from aqueous acetone

or aqueous acetonitrile, a relatively nonpolar solvent such as petroleum ether achieves high recovery of the analytes and fewer nonfatty matrix components partition into the organic phase.[8,9,27,37,106,107] DCM, or DCM–petroleum ether (1:1 v/v), are more appropriate to recover pesticides with a wider polarity range.[22–26,38] With acetone as the extracting solvent of fruits and vegetables, after the partition into DCM about 0.5–2 mg of coextractives per gram of sample remain in the extract. Adjusting the pH to 7, generally with phosphate buffer, in the extraction or partition step prevents the partitioning of endogenous acids and is useful to reduce coextractives from fruits and vegetables, especially citrus fruits.[21] For vegetable samples extracted with methanol or ethanol, the analytes are usually partitioned into toluene.[30–32]

The LLP procedure is normally carried out in a separatory funnel, in which the solvent of higher density forms the lower layer. Only one separatory funnel is needed to perform multiple extractions, while solvents less dense than water (e.g. ethyl acetate) require multiple separatory funnels to perform multiple extractions. Emulsions (especially with sugar- and pectin-rich vegetables), manual labor, high glassware needs, and lengthy operation are the main drawbacks of traditional LLP.

Other ways of getting rid of the aqueous phase include the ''salting out'' process to separate the acetonitrile,[20,21] or the addition of water-immiscible solvents, such as DCM–*n*-hexane (1:1 v/v) or ethyl acetate, or a mixture thereof, to separate a mixture of solvents containing the analytes.[15,108] This type of partition leads to the separation of polar solvent mixtures, so that OC, PYR, and more polar compounds can be recovered. The operation is normally carried out in the same vessel used for the extraction. The volume of solvent separated should be recorded and taken into account in the calculation of the results.

Instead of the labor- and time-consuming operation using separatory funnels, the same type of partition can be advantageously carried out by absorbing a portion of the aqueous acetone extract into cartridges filled with macroporous diatomaceous material.[109] The material acts as a support where the partition takes place. Then, acetone is partially evaporated by an upward stream of nitrogen, and the cartridge is eluted with petroleum ether, DCM, or mixtures thereof. With different combinations of nitrogen flow and time, different amounts of acetone remain on the columns, and, combined with the selected solvent, the polarity range of the compounds that can be recovered is controlled. This also provides some control over the amount of coextractives removed from the cartridge. Low to medium polarity compounds, such as OC and PYR pesticides, can be recovered by reducing the acetone content to ca. 50% of the original (2:1 acetone–sample to 1:1 acetone–sample) and eluting with low polarity solvents, such as petroleum ether or petroleum ether–DCM (75:25 v/v).[109] Unlike using the separatory funnel, this approach uses disposable items, is simple and straightforward, and avoids emulsions.

Another way of recovering pesticide residues from aqueous acetone or aqueous acetonitrile is by SPE. The solution resulting from the extraction is diluted with water to bring the solvent concentration down to ca. 5–10% and, then, is passed through a lipophilic cartridge, such as PS–DVB[29] or C_{18},[110] or a C_{18} extraction disk.[111] Pesticide residues are retained in the solid phase while the aqueous phase is discarded. Pesticide residues are eluted from the cartridge with a solvent, for instance, ethyl acetate[29] or acetone–ethyl acetate (1:1 v/v).[111]

4.1.2 Fatty Samples

The extraction of fatty samples, which can include both plant (e.g. avocado) or animal tissues, commonly results in significant amounts of coextracted lipidic material. The separation of pesticide residues from the bulk of the coextracted fat is a mandatory step before an instrument-based identification/determination step. Classically, multiple separatory funnel partitions between immiscible solvents are used. The most commonly used solvent pair is *n*-hexane–acetonitrile,[8,9] whilst *n*-hexane–dimethylformamide (DMF)[112] and *n*-hexane–dimethyl sulfoxide (DMSO)[113] are also useful. Most of the lipidic material remains in the nonpolar solvent (e.g. *n*-hexane) while pesticide residues are partitioned into the polar solvent (e.g. acetonitrile) of the above-mentioned pairs. Unfortunately some of the most nonpolar pesticides such as HCB, mirex, and highly chlorinated PCBs also partition into the nonpolar phase. The so-called p-value, defined as the fraction of the analyte partitioning into the nonpolar phase of an equi-volume two-phase system, gives a measure of the ability of the polar solvent to extract the analyte of interest.[114] The higher the p-value, the lesser the partitioning into the polar solvent. OC and PYR pesticides show a wide range of p-values in the *n*-hexane–acetonitrile partition system, ranging from 0.91 (mirex) (lipophilic compound) to 0.035 (endosulfan sulfate) (more polar compound).[114] The p-values of some of the OC and PYR pesticides are reported in Table 3. The recovery into acetonitrile is almost complete after four partition stages using a 1:2 nonpolar–polar solvent ratio as it is normally applied.[8,9] However, the recovery of HCB and mirex (the most lipophilic OC pesticides) is barely satisfactory (ca. 70%). Being more polar than OC, PYR pesticides strongly partition into acetonitrile. Up to 3 g of fat dissolved in 15 mL

Table 3 p-Values of some OC and PYR pesticides between *n*-hexane, or isooctane, and acetonitrile

OC *n*-Hexane–acetonitrile[a]		PYR Isooctane–acetonitrile[b]

[b] p-Values from Argauer et al.[115]

of *n*-hexane can be extracted with four 30-mL fractions of acetonitrile.[8,9] However, the removal of lipidic material is largely dependent on the type of fat. The removal is better with saturated fats, while it is less satisfactory with unsaturated oils such as fish oils. Furthermore, secondary components of fats, such as sterols and tocopherols, are extracted into the polar solvent and should be removed by further cleanup steps before GC with electron capture detection. MS detectors may avoid this problem.[115]

In this approach, once pesticides have been extracted into acetonitrile, this solvent is generally exchanged because it is not amenable to most of the subsequent analytical steps, and interferes with electron capture detection. Three main methods have been used.

First, acetonitrile can be concentrated to dryness by typical rotary evaporation techniques under reduced pressure. The azeotropic distillation of acetonitrile after the addition of methanol (acetonitrile–methanol, 4 : 1 v/v)[66] or addition of *n*-hexane (acetonitrile–*n*-hexane, 1 : 3.5 v/v)[21] helps to lower the boiling point and to reduce losses of volatile analytes (e.g. HCB). The small amount of lipidic material present in the acetonitrile acts as a ''keeper'', i.e. reduces or avoids the loss of lipophilic analytes by solubilizing them during the concentration process. In this way, all the components present in the acetonitrile remain in the extract and a different solvent is used for the next cleanup step.

In a classical method, acetonitrile is diluted with saline solution until its concentration in the solution is about 15% and pesticide residues are extracted from the aqueous acetonitrile solution into a low-boiling solvent by multiple partitioning steps. This type of partitioning is termed ''back'' extraction. For low polarity lipophilic compounds, such as OC and PYR pesticides, low polarity petroleum ether is appropriate, because it removes less coextractives from the aqueous phase.[8,9] For more general multiclass methods, DCM is more suitable. The petroleum ether solution can be easily concentrated and subjected to further cleanup steps after solvent exchange, if necessary. In this way, some more polar components present in the acetonitrile extract could be removed by the aqueous phase.

In a third method, acetonitrile is diluted with water until its concentration is about 30% in water and the solution is passed through a reverse-phase cartridge (usually C_{18}) that retains lipophilic pesticides (and other compounds). After drying the cartridge, OC and PYR pesticides can be recovered by eluting with a low-polarity solvent mixture such as toluene–*n*-hexane (3 : 97 v/v), which is suitable to be transferred on-line to an adsorption chromatography cartridge.[51]

As in the case of nonfatty samples, a separatory funnel can be avoided in the *n*-hexane–acetonitrile partitioning step by absorbing the *n*-hexane solution into a macroporous diatomaceous material.[116–118] This acts as a support for the partition process, which is carried out by eluting the bed with acetonitrile saturated with *n*-hexane. Compared with the separatory funnel, the solid matrix partition process is simple and rapid and uses small volumes of solvent (typically 1 g of fat requires 15 mL of acetonitrile and 4 mL of methanol for azeotropic distillation). It is also able to satisfactorily recover from relatively nonpolar compounds such as OC and PYR to polar OP pesticides, while HCB shows a slightly lower recovery (ca. 60%) than the separatory funnel operation.[116] In these applications, a C_{18} cartridge is used downstream to the partition cartridge for in-line further removal of fatty matrix.[116–118] The recovery of 15 OC pesticides from 1 g of soya oil spiked at different levels is reported in Table 4.

In other methods the partition process is carried out by dispersing the extracted fat or fat solution over a chromatographic material that is used to retain the fat and from which OC pesticides are recovered by eluting with acetonitrile or water–acetonitrile mixtures. Alumina eluted with water–acetonitrile (20 : 80 v/v),[119] Florisil eluted with water–acetonitrile (10 : 90 v/v)[48] (both followed by back extraction of pesticide residues into petroleum ether), Celite eluted with DMSO,[40] C_{18} eluted with acetonitrile,[62] or silica gel over PS–DVB eluted with acetonitrile[29] have been found to be useful for this purpose.

4.2 Size-exclusion Chromatography

SEC (often referred to as gel permeation chromatography) is one of the most commonly used cleanup steps to separate pesticide residues from high molecular weight coextractives and fats. The most popular column material in SEC is a cross-linked styrene divinylbenzene (DVB) resin which is eluted with solvent mixtures such as toluene–ethyl acetate or cyclohexane–ethyl acetate

Table 4 Recovery values of 15 OC pesticides extracted from ca. 1 g soya oil spiked at different levels and analyzed after Extrelut-3/C_{18} cleanup followed by Florisil adsorption chromatography, according to the method in Di Muccio et al.[116]

for vegetable extracts, and cyclohexane–DCM or *n*-hexane–DCM for fats.

The predominant mechanism of separation relates to the difference in the molecular size between many of the coextractives and the pesticide residues, which generally have molecular weights lower than 500 amu. The resin also exhibits an adsorption mechanism which is mostly masked by the polar solvent used in the mixture. The larger compounds such as fats, oils, and the major part of vegetable coextractives elute earlier (''dump'' fraction) than the pesticide residues (''collect'' fraction). One of the major features of SEC is that it is a nondiscriminative cleanup very useful in multiclass multiresidue methods. Large columns (ca. 45 cm × 2.5 cm ID) have been used that are eluted at $5\,mL\,min^{-1}$ and require about 350–400 mL per sample (''dump'' fraction + ''collect'' fraction + column wash). The collect fraction is about 100–150 mL.[8,9,26,120,123] Large columns (300 mm × 19 mm ID) eluted with DCM at $5\,mL\,min^{-1}$ and with ''collect'' fraction of 20 mL are used in the cleanup of OC and PYR pesticides by high-performance size-exclusion chromatography (HPSEC).[28] The recovery of 15 OC pesticides from 500 mg of spiked soya oil through HPSEC cleanup is reported in Table 5. Also, smaller columns (10 mm ID) for low-pressure chromatography[33] or 7.8 mm ID for HPSEC have been used both for OC and PYR pesticide cleanup and allow a substantial 10-fold saving of time and solvent.[65,124] The column is also reusable, and SEC lends itself to automation. Apart from requiring expensive instruments, SEC is a sequential cleanup procedure, limiting the number of samples that can be processed in a given period of time.

After SEC cleanup (and a concentration step), the nonfatty sample extracts are normally suitable for GC analysis using a selective detector such as an electron capture detector (ECD), a thermionic nitrogen–phosphorus detector (NPD), and/or a flame photometric detector (FPD) without further cleanup. However, for the

determination of OC pesticides by GC/ECD at the lowest levels a further cleanup by adsorption chromatography is often necessary.[121]

SEC offers the opportunity of diverting the ''collect'' fraction directly to a cartridge of chromatographic material for further cleanup on-line. For instance, when low polarity solvent mixtures are used in the SEC of fats, the collect fraction can be purified by adsorption chromatography by passing it through a silica gel cartridge.[125] This avoids the usual sequence of operations, such as collection of the fraction, concentration, solvent exchange, and quantitative transfer to the adsorption column. In a similar application for vegetables, the collect fraction can be passed through a cartridge of active charcoal for on-line removal of pigments.[126] The removal of high molecular weight components by SEC, that are not necessarily removed by adsorption chromatography cleanup, is beneficial to the subsequent GC determination in that it avoids contamination of the injection port and column. Furthermore, micro SEC can be coupled on-line to a gas chromatograph by means of valve switching technology and using a gas chromatograph equipped with a large volume injection system.[127]

4.3 Sweep Codistillation – Assisted Distillation

Sweep codistillation is a technique of cleanup based on thermal degradation of the coextractives including lipidic material and distillation/entrainment of the pesticide residues. In classical operation, the solvent solution of the raw extract (maximum 1 g of fat) is injected into a hot tube filled with glass beads in a stream of nitrogen. Most of the coextractives and the lipidic material adhere to the filling material. Further injections of solvent into the tube elute the pesticide residues via distillation with the hot stream of the nitrogen (sweep codistillation). In more recent developments, the fat is not degraded, but rather deposited in a special void tube held at high temperature. The fat spreads as a thin film over the inner walls of the tube, which is swept by nitrogen, and no injections of solvent are necessary (assisted distillation).[128–130]

To recover the pesticide residues, the effluent is passed through a cold trap and then transferred off-line for a further cleanup. In commercially available systems designed for OC pesticides, the effluent is passed on-line through a cartridge of Florisil for further adsorption cleanup prior to the GC/ECD analysis.

The technique is mainly suited to OC and other fairly stable compounds due to the high temperature involved. Temperatures are in the range of 200–250 °C and typical nitrogen flow is in the range of 200–250 mL min^{-1}. Apparatus is commercially available for processing several samples in parallel.

4.4 Column Chromatography

Adsorption chromatographic cleanup separates the coextractives on the basis of their polarity. Thus, it is appropriate for separation of low polarity compounds such as OC pesticides from the more polar coextractives present in the extracts. Adsorption chromatography under gravity alone was the cleanup of choice in the early days of pesticide residue analysis and it is still widely used. When instruments were not so sensitive as today and large analytical samples were extracted, a large amount of coextractives had to be removed. Consequently columns consisted of 10–20 g of adsorption material which required two to three fractions of 100–200 mL solvent each.

Now, instrumental sensitivity satisfactorily allows the use of adsorption cleanup on smaller columns (1–5 g of adsorbent eluted with fractions of 10–50 mL) as the sole cleanup when a small sample aliquot is extracted, or as a supplemental cleanup after the large-capacity cleanup steps already described.

Column chromatography as cleanup can also be used to collect a single fraction containing a wide range of pesticides with appropriate solvent(s). This approach is mostly useful in multiresidue methods to analyze for as many pesticides as possible. Of course, this approach requires sufficient resolving power in the identification step. However, the fractionation of the extract simplifies analyte identification and reduces the number of potential interferences in the collected fractions. Furthermore, the appearance of tentatively identified analytes in the expected fraction adds further evidence to the analyte confirmation. However, fractionation of the extract increases the number of identification processes. With adsorbents such as Florisil, alumina, and silica gel the reliability of the fractionation mostly relies on controlling and maintaining the right degree of activation/deactivation.[9,45,131] For this reason, adsorption columns and cartridges are used for just a single sample and are not reused.

In the case of OC and PYR pesticides, the most frequently used adsorbents are Florisil, alumina, and silica gel. Depending on the particular application, these sorbents can be used either ''activated'', i.e. heated at a temperature high enough to release most of the moisture, or ''deactivated'' with addition of 1–10% (w/w) water. The more active the material, the more coextractives and fat that are retained. Partial deactivation allows the use of a less polar eluent, while maintaining sufficient retention of the fat. OC pesticides are eluted with hydrocarbon solvents or low polarity mixtures, but more polar eluting mixtures are required to recover oxygenated OC pesticides, such as dieldrin, endrin, heptachloroepoxide, and oxychlordane, while PYR pesticides require significantly more polar

eluents. However, more polar eluents generally lead to "dirtier" fractions. Apolar fractions are almost free of lipidic material, while a few milligrams may appear in the polar ones. Water deactivation allows the use of less polar eluents. Hence 10 g of 5% water-deactivated Florisil, eluted with 200 mL of diethyl ether–petroleum ether (6 : 94 v/v), has been used to clean up PYR extracted from wheat and vegetables.[37]

With Florisil macrocolumns (ca. 20 g) two eluting schemes are well known and are continuously updated with a number of new pesticides. In the first scheme, three fractions are collected eluting with 6%, 15%, and 50% ethyl ether in petroleum ether, while in the second scheme three fractions, consisting of 20% DCM in *n*-hexane, 50% DCM + 0.35% acetonitrile in hexane, and 50% DCM + 1.5% acetonitrile in *n*-hexane, are used.[8,9]

Examples of Florisil minicolumns include: (1) a 2.5-g column eluted with *n*-hexane–benzene–ethyl acetate (180 : 19 : 1 by vol.) for OC pesticides,[52] and with *n*-hexane–benzene–ethyl acetate (176 : 19 : 5 by vol.) for PYR pesticides;[66] (2) a 4-g column eluted with one fraction of 50% DCM + 1.5% acetonitrile in *n*-hexane for OC and PYR;[9] (3) a 5-g column of 10% water-deactivated Florisil eluted with diethylether–*n*-hexane (4 : 96 v/v) for OC.[132] The fractionation of 28 OC pesticides and 20 PCBs from a 2.5-g Florisil column eluted with a three-eluent scheme is reported in Table 6. Application of Florisil cleanup to PYR pesticides also include: (1) a 10-g column eluted with 100 mL of ethyl acetate–*n*-hexane (3 : 7 v/v);[133] (2) a 6-g column eluted with 6 mL of *n*-hexane–diethyl ether (7 : 3 v/v);[134] (3) a 0.5-g minicolumn eluted with 5 mL of toluene;[30] (4) a minicolumn of 0.5 g of Florisil + 0.04 g of active charcoal eluted with 5 mL of toluene.[31] A minicolumn of 4 g of Florisil + 1 g of active charcoal eluted with 40 mL of toluene–acetonitrile (98 : 1 v/v) has been used for the cleanup of extracts from vegetables.[32] A similar, smaller column (1.6 g Celite + 0.4 g charcoal eluted with 50 mL of acetonitrile–toulene (3 : 1 v/v)) is the cleanup used in a multiclass, multiresidue method for fruits and vegetables.[20]

Alumina in large columns (15 g of acidic alumina eluted with 160 mL of DCM) has been used as a very common cleanup step before the GC/ECD determination of OC and PYR pesticides in grains.[38] A minicolumn of 1 g of 10% water-deactivated alumina has been used for the separation of OC pesticides from 70–100 mg of fat.[135] However, the control of the deactivation process is done by recovery trials of critical compounds and, due to poor batch-to-batch reproducibility, the deactivation has to be repeated with new batches.[76]

Popular multiresidue schemes with silica gel include: (1) a 5-g column eluted with five fractions of *n*-hexane, *n*-hexane–benzene (4 : 6 v/v), benzene, benzene–ethyl acetate (1 : 1 v/v), and ethyl acetate to elute a diversity of

Table 6 Fractionation of OC pesticides and PCB from a column of 2.5 g activated Florisil eluted with a three-solvent elution scheme in the presence of 50 mg soya oil

pesticides;[23] (2) a 1-g column of 1.5% water-deactivated silica eluted with five fractions of increasing polarity (*n*-hexane–toluene (65:35 v/v), toluene, toluene–acetone (95:5 v/v), toluene–acetone (80:20 v/v), and acetone) for over 400 compounds including OC and PYR;[10,26] and (3) a 1-g column eluted with four fractions of *n*-hexane, benzene–*n*-hexane (60:40 v/v), benzene, and ethyl acetate–benzene (50:50 v/v), to separate 50 OC pesticides and PCB.[136] An application for PYR pesticide residues from fruits and vegetables is based on a 5-g silica column eluted with 25 mL of *n*-hexane–DCM (4:1 v/v) and 60 mL of DCM (contains the analytes).[137] An application of silica gel to OC, OP, and triazines in wine is based on a 15-g column eluted with 40 mL of *n*-hexane, 16 mL *n*-hexane–benzene (1:1 v/v) and 50 mL of acetone.[74] Sequential application of Florisil cleanup and silica fractionation has been used for PCBs in human serum.[44]

4.5 Solid Phase Extraction Chromatography

Currently, ready-to-use cartridges filled with 0.1–1 g of classical adsorbents (alumina, silica, Florisil, carbon), the so-called SPE cartridges, are increasingly used to miniaturize the cleanup; this saves solvents and time, and allows automation of the cleanup step.

C_{18} cartridges are used to reduce or retain lipophilic coextractives when acetonitrile or aqueous acetonitrile extracts from either fatty[46,49,51,116,117] or nonfatty samples[21,110] are passed through. It has been noted that most pesticides elute off a C_{18} cartridge with an eluent composition of acetonitrile–water (75:25 v/v) (which is about the composition of the aqueous acetonitrile from the extraction of vegetable samples), while lipids and other highly lipophilic coextractives are retained.[21] In a different way, aqueous acetone,[29] or aqueous acetonitrile,[110] resulting from the extraction of vegetables, can be further diluted with water and passed through a lipophilic C_{18}[110] or PS–DVB[29] cartridge to retain the analytes. After retention, C_{18} and PS–DVB cartridges are dried with a nitrogen stream and the analytes are recovered with solvents such as ethyl acetate[29] or toluene–petroleum ether (3:97 v/v).[49,51] The latter, being of low polarity, can be passed directly to a Florisil cartridge for subsequent adsorption cleanup,[49,51] avoiding the usual sequence of linking steps (collection, concentration, solvent exchange, quantitative transfer).

Florisil is used to remove polar coextractives in the analysis of both fatty[49,51] and nonfatty[29] sample extracts. In an application of Florisil SPE cartridges to OC in fish, crab, and milk the eluting mixture was diethyl ether–petroleum ether (2:98 v/v),[49,51] while it was acetone–*n*-hexane (15:85 v/v) for PYR pesticide residues in paddy rice.[138] Alumina SPE has also been used for adsorption cleanup of fatty extracts.[118]

SPE-NH_2 has also been used in normal phase cleanup in multiresidue methods for nonfatty[15,21] and milk samples.[46] It is usually eluted with DCM–methanol (97:3 v/v)[46] or DCM–methanol (99:1 v/v).[15]

In a multiresidue method based on acetonitrile extraction, after separating the water with the "salting out" procedure, a portion of the acetonitrile extract is cleaned up with a minicolumn of 2 g of charcoal–Celite (1:4 w/w) or on a carbon SPE cartridge of 500 mg. The pigments are mostly retained while the pesticides are eluted with acetonitrile– toluene (3:1 v/v).[20] It is noteworthy that HCB is poorly or not recovered through carbon, depending on the type of material. Such a cartridge has been used also downstream from an SEC column eluted with cyclohexane–DCM (1:1 v/v) to trap pesticides for subsequent SPE cleanup.[126] Another way of removing pigments from fruits and vegetable extracts is the use of an SAX (strong anion exchanger) or an SAX/PSA (propylethylenediamine – silica): the extract is applied in DCM and eluted with DCM.[54]

The great advantage of cleanup on an SPE cartridge is that it is amenable to robotic manipulation for unattended processing of large sequences of extracts. Also SPE cartridges are ready-made, disposable, and reduce solvent consumption, time, and labor.

4.6 High-performance Liquid Chromatography

Semipreparative HPLC on a column of 250 mm × 9.2 mm ID filled with porous spherical silica particles and eluted with 20% DCM in *n*-hexane has been used to separate five OC pesticides and PCB from 300 mg of butter fat.[139] By using column switching technology, fully automated sample cleanup and fractionation of 10 OC pesticides and PCB from 45 mg of fat was achieved by normal phase chromatography using a short column and an analytical column of silica gel.[45] A rapid automated off-line cleanup on a silica gel HPLC column has been reported for the cleanup of 45 mg of fat in 32 min per sample.[140] Advantages include high separation power and reproducibility, and reusability of the column.

An automated sample cleanup and fractionation has been used for the analysis of mussel extract using normal phase high-performance liquid chromatography (NPHPLC) with a column of silica (150 mm × 3.9 mm ID) eluted stepwise with 4 mL each of *n*-hexane, *n*-hexane–ethyl acetate (99:1 v/v), and ethyl acetate for the separation and collection of compounds of different polarity.[141] NPHPLC on aminopropyl silica has been used after lipid separation by SEC for the cleanup and group separation of PCB and OC pesticides in cod liver oil. The column was eluted with two fractions: the first (10 mL of *n*-hexane) elutes the nonpolar PCB,

HCB, DDE, and mirex, and the second (32 mL of *n*-hexane–DCM (90 : 10 v/v)) elutes the more polar HCH, DDD, DDT, and chlordane.[142]

4.7 Thin-layer Chromatography

Due to its high separation capabilities, TLC can also be used as a mini preparative, highly selective cleanup. Crude or partially cleaned up extracts equivalent to 2–10 g of product (acetone extraction and partition into DCM) can be applied bandwise on a standard 20 mm × 20 mm × 0.25 mm silica gel plate. After the development, compounds of interest can be recovered from the plate by scraping the band at the appropriate retention factor (R_f) (identified by running the target compound(s) alongside at higher concentration) and eluting the silica material with a suitable solvent. Compound(s) recovered are highly cleaned up and are suitable for identification/determinative techniques. The agreement between the R_f and the response from the identification techniques adds further evidence for confirmation of the tentatively identified compounds at residue level. As a cleanup step, TLC has high separation power but low capacity and, therefore, complements a high-capacity, low resolving power cleanup, such as SEC or partition processes.[8,143] TLC is inconvenient but can increase throughput due to parallel operation.

4.8 Degradative Cleanup

Degradative cleanup for samples of plant and animal origin can be accomplished by chemical treatment which converts many coextractives into chemical species that are no longer extractable, or permits their easy removal with a selective process.

Due to their relatively high chemical stability, strong degradative cleanup has often been applied to extracts for the analysis of OC pesticides. Relatively mild degradative cleanup is conceivable for PYR and other classes of pesticides.

Concentrated sulfuric acid treatment is a classical method to destroy organic matter in raw extracts. It has been applied either by shaking a solution of the extract with sulfuric acid,[144,145] or by passing the solution through a column of inert diatomaceous material.[146] The recoveries of 22 OC compounds through a sulfuric acid impregnated Extrelut cartridge are reported in Table 7. A small amount of silica gel impregnated with concentrated sulfuric acid has been used as the bottom layer in a bilayer MSPD column for the extraction of PCBs in fish.[147]

Alkaline treatments have been used to saponify and remove the fatty material. They can be given either by passing the solvent solution through a column of MgO mixed with diatomaceous material,[8] or by treatment with 10% KOH in ethanol.[43,145] In the first case the solvent solution is directly amenable to the next determinative step, while in the second case an extraction into an organic solvent is carried out. An example is the saponification applied to the analysis of PCBs in fats and oils.

Table 7 Behavior of 22 OC compounds through an Extrelut cartridge charged with 1 mL of either 95% or 90% sulfuric acid, eluted with 10 mL of light petroleum, according to the method in Di Muccio et al.[146]

Compounds	Amount (μg)	Average recovery ± SD ($n = 6$) (%)

[a] Recovered as endrin ketone, which appears as a peak with a retention time longer than that of the parent compound.
[b] Not investigated.
NR, not recovered.
Unpublished data from the laboratory of the author.

Both sulfuric acid and alkaline treatments have been used either as the sole cleanup for the analysis,[42,43] or as a supplemental cleanup after some of the main cleanup steps described above.

Degradative cleanup, however, can introduce some transformation of the analyte(s) of interest. Most OC pesticides including PCNB and PCB are stable under acidic conditions except dieldrin, which is destroyed; endrin, which is converted into endrin ketone; and methoxychlor, which is partially destroyed.[146]

HCB, cyclodienic pesticides (heptachlor, heptachlor-epoxide, aldrin, dieldrin, endrin, and mirex) and DDE are stable under alkaline conditions at ambient temperature, while PCNB is slowly degraded, and DDT, DDD, and methoxychlor are dehydrochlorinated to the corresponding olefins.[145] Dicofol is fairly stable at ambient temperature,[145] but it is converted to DCBP in

strong alkaline conditions.[5] HCHs are converted into trichlorobenzenes.[148] As esters, PYR pesticides are degraded under alkaline conditions.

Silica gel, alumina, or Florisil impregnated with silver nitrate have been used for the removal of some sulfur-containing compounds from extracts of onions and kale.[149] By the addition of $NaBH_4$ prior to sample extraction with acetonitrile, nearly all matrix interferences (organosulfur compounds) can be eliminated from green onion samples.[21]

Oxidative cleanup with $KMnO_4$ solution has been used in the analysis of vegetables.[150]

The alteration of some analyte(s) may be used to remove or separate them from other analytes, for instance, the oxidation of DDE to DCBP and its separation by adsorption chromatography can eliminate this interference in the analysis of PCB.[6] Also this approach can be used to convert the analytes into species with better chromatographic, sensitivity, and selectivity properties. Derivatization of the analytes into species whose detection is a confirmation of identity is also sometimes necessary. For instance, detection of endrin ketone after acid treatment is diagnostic for endrin, and detection of a specific late-eluting peak after reaction with a hydrobromic acid–acetic anhydride mixture is diagnostic for dieldrin, whose epoxide ring is opened under these conditions.[151] HCB can be converted into later-eluting monoisopropoxypentachlorobenzene and diisopropoxytetrachlorobenzene for confirmation of identity.[152] The formation of compounds with longer retention times in GC is beneficial because usually most of the matrix interference appears in the early portion of the chromatogram.

As stated above for dicofol,[63] degradation of analytes during the analytical process is also possible.

In the analysis of PCB and OC pesticides in environmental samples, especially soil and sediments, it is necessary to remove elemental sulfur to obtain a good GC/ECD chromatogram. The removal is carried out by activated copper powder,[71] with tetrabutylammonium sulfite, or with SEC.[7]

5 IDENTIFICATION AND DETERMINATION

5.1 Gas Chromatography

OC and PYR, as well as other classes of pesticides which have relatively low molecular weight with sufficient volatility, are most commonly analyzed by GC. A great number of developments and improvements in GC and related detectors has been made in connection with the analysis of pesticide residues in food and environment. The relative simplicity and ease of operation, together with the high separation power and an array of sensitive and selective detectors, make GC the technique of choice for determination of thermally stable pesticides.

5.1.1 Packed Columns

The first GC applications involving pesticide analysis were developed on packed columns. Early columns were generally glass tubes 1–2 m long, 2–4 mm ID, filled with a solid, high surface material covered with 1–5% (w/w) of thermally stable, low volatility polymers. A variety of stationary phases including methyl silicone (DC-200, OV-1, OV-101, SE-30), methyl phenyl silicone (OV-17, DC-710), fluoropropyl silicone (QF-1, OV-210), cyanopropyl silicone (XE-60, OV-225), polyethers (Carbowax 20 M), and polyesters (DEGS, NPGS) allowed a diversification of selectivity, which can be further expanded by packing the columns with mixed packings, such as 5% DC-200 + 7.5% QF-1, 1.5% OV-17 + 1.95% QF-1, 1.5% SP-2250 + 1.95% SP-2401, 5% OV-101 + 3% OV-225, and 5% OV-61 + 3% XE-60 + 5% QF-1.[8,9,11,151–153] The chemical composition of the main stationary phases and trade codes are reported in Table 8.

Although packed columns have almost been entirely superseded by capillary columns, they could have useful application in the screening of a few target analytes in dirty extracts. Indeed, the injection of coextractives into the first, hot portion of the packing material provides an extra cleanup by irreversible adsorption or thermal degradation. However, thermally labile compounds suffer from the activity of the packing material.

5.1.2 Capillary Columns

Nowadays, pesticide residue analysis is almost always carried out on fused silica capillary columns. In this approach, columns from 10 to 60 m with IDs of 0.18–0.53 mm (0.18 mm, ''microbore''; 0.25 mm, ''narrow-bore''; 0.32 mm, ''wide-bore''; 0.53 mm, ''megabore'') are commercially available. Smaller diameter columns have greater separation capabilities, but also have a smaller sample capacity and limited lifespan. The liquid stationary phase is normally chemically bonded to the inner surface of the columns, and film thicknesses used in pesticide residue analysis are typically in the range 0.25–1.5 μm. The special preparation of the inner surface and the coverage of the film give a high degree of inertness that allows the analysis of relatively labile and/or polar compounds. A variety of polymers of similar nature to the packed columns are available for capillary columns, and even specially prepared columns are available to suit specific separations, such as the ''608'' series columns for OC pesticides listed in EPA Method 608.[154]

Table 8 Chemical composition and trade codes of the most common GC stationary phases

Chemical composition	Trade code
100% Dimethyl polysiloxane	007-1, CP-Sil 5CB, DB-1, DB-lht, HP-1, HP-101, OV-1, RSL-150, RSL-160, Rtx-1, SE-30, SPB-1, SPB-Sulfur, ULTRA-1, SP-2100, BP-1, DC-200, AT-1, ATS-1, EC-1

Biscyanopropyl, cyanopropylphenyl polysiloxane	CP-Sil 84, Rtx-2330, Rt-2330, SP-2330, SP-2331, SP-2560, SP-2380, AT-SILAR
Poly(ethylene glycol)	007-CW, Carbowax 20M, CP-Wax 52CB, DB-WAX, HP-20M, HP-Wax, lnnowax, Omegawax, Stabilwax, AT-WAX, EC-WAX, SUPELCOWAX-10, SUPEROX II, BP-20, ATS-WAX
Poly(ethylene glycol) modified with acids	007-FFAP, CP-Wax 58CB, DB-FFAP, HP-FFAP, Nukol, OV-351, SP-1000, Stabilwax-DA, SUPEROX-FA, BP-21, Stabilwax-DB, CAM, Carbowax Amine, AT-1000, EC-1000

The type and dimension of the column depend on the type of analysis and analyte/matrix combination. In routine pesticide analysis of fruits and vegetables, megabore columns of 15 m × 0.53 mm ID × 0.8–1.5 μm film thickness provide sufficient separation in a short time combined with a good capacity and ease of operation.[30,66] In large, multiclass, multiresidue methods for monitoring pesticide residue in foods, columns of 30 m × 0.25 mm ID × 0.25 μm film thickness are most commonly used.[20,28,54,57,153,155] For highly demanding environmental analysis regarding the analysis of complex mixtures of environmental contaminants such as PCBs and camphechlor (toxaphene), columns of 60 m × 0.18–0.25 mm ID × 0.18–0.25 μm film thickness are used.[44,156] The most widely used stationary phases are the 100% dimethyl polysiloxane (''code-1''), the 5% diphenyl–95% dimethyl polysiloxane (''code-5''), the 35% diphenyl–65% dimethyl polysiloxane (''code-35'' and ''code-608''), the 50% diphenyl–50% dimethyl polysiloxane (''code-50'' and ''code-17''), and the 14% cyanopropylphenyl–86% dimethyl polysiloxane (''code-1701'') phases. Each phase has a particular selectivity and is better suited to particular separations. The most commonly sought OC pesticides are better separated on a ''608'' phase, including the critical pair DDE–dieldrin. The group of early eluting HCB and HCH isomers is better separated on a ''1701'' phase. Some pairs of OC pesticides, including DDE–dieldrin, *cis*-heptachloroepoxide–oxychlordane, *cis*-chlordane–*trans*-nonachlor, *o*,*p*′-DDT–endrin, and β-endosulfan–*p*,*p*′-DDD, are considered critical. A number of critical pairs are found in complex PCB mixtures, for instance, PCB 55/60, PCB 138/178.[44] Analyses on columns of different polarity are usually carried out to resolve critical pairs.

Continuing research is dedicated to the development of new phases to meet the stringent requirements of the separations needed for complex mixtures of OC compounds such as PCB and toxaphene in environmental samples.[7,142,156] Toxaphene consists of several compounds with a different degree of chlorination and most of them are chiral. Enantiomers often have different toxic and degradative properties. Enantiomer separation has been carried out on chiral capillary columns.[157] Tandem columns, i.e. systems made of a combination of a column that gives isomer-selective separation and a column that gives enantiomer-selective separation, can be optimized for the isomer- and enantiomer-selective separation of toxaphene.[158] PYR are currently analyzed by using conventional GC phases where only the separation of the stereoisomers occurs.[30,31] For instance, cypermethrin

(with three asymmetric carbon centers giving eight enantiomers) shows only four peaks corresponding to the four pairs of enantiomers, eluting in the order *cis*, *trans*, *cis*, *trans* from a low-polarity column.[153]

Being chemically bonded to the surface, the stationary phase is more stable and, after being subjected to high-temperature conditioning, releases a low ''bleeding'' even at high temperature, so that detectors can be operated at higher sensitivity and programmed temperature operations are possible and still maintain a flat baseline. Temperature programming and the high resolving power of the capillary columns allow the analysis of a wide variety of analytes in complex mixtures in a single run.

5.1.3 Injectors

While injection into packed columns is quite simple, special injectors and injection techniques have been developed to fully exploit the separation power of capillary columns. Injection can be carried out either in a ''liner'' (an injector chamber held in the injector oven to which the column is connected) or ''on-column''. Injection into a liner is carried out with conventional microsyringes through a polymeric rubber septum. On-column injection into narrow- and wide-bore columns is carried out through special valves and requires tiny needles and special alignment systems. However, ''liner''-type on-column injection is possible with conventional techniques into the first portion of a megabore column held in the injector oven. Autoinjectors also work more simply and reproducibly when injection is made into liners or on megabore columns.

The site of injection, either the liner or the beginning of the column in on-column operation, is located in the injector oven. At the time of injection the temperature can be kept either high enough to vaporize all the components (hot or flash vaporization) or suitably low to allow the vaporization of the solvent only, with the analytes being vaporized on temperature programming (temperature programmable injectors). The injection chamber (the liner) and the column can be connected so that all the sample injected is transferred to the column, or part of the vapor produced upon injection can be ''split'' and vented outside (split injectors). In pesticide residue analysis, as in general in trace analysis, one is interested in maximum sensitivity. Thus, split injectors are operated in ''splitless'' mode. In this mode, the split vent of the injection chamber is closed for about a minute to allow the almost quantitative transfer of the sample into the column, and then the split vent is opened to sweep the residual vapor from the injection chamber.

Regardless of the type of injection, the vapor produced by the usual injection volume (1–3 μL) would flood the column and spread the analytes along a great length of the column unless special operating techniques were used. To refocus the analytes into a narrow band at the beginning of the column, the temperature of the column oven is kept relatively low (cold trapping) while the analytes are transferred from the injection site into the column. Furthermore, with proper selection of the column temperature with respect to the boiling point of the solvent injected, solvent vapors are temporarily condensed, which leads to a temporary increase of the film thickness of the stationary phase. This leads to the enhancement of the retention properties of the column in that zone and refocusing effects on the analytes (solvent effect).

Injection is usually done through a septum made of special silicone polymers. At high temperature, a certain bleeding occurs and possibly leads to ghost peaks in the chromatogram. Thus, septum injectors in trace analysis are normally equipped with a septum purge line, i.e. a small stream of the carrier gas that sweeps the inner face of the septum to vent much of the bleeding.

Usually volumes of 1–3 μL are introduced, but this depends on the type of injector. Hot vaporizing injectors should have liners with sufficient volume to accommodate the vapor, or else contamination of the carrier gas line can occur due to backflushing. Larger volumes give longer vapor residence time in the liner and contact with hot surfaces can enhance degradative effects on the analytes. To decrease the residence time, hot vaporizing injectors are better operated with megabore columns with flow in the range 5–10 mL min^{-1}. To increase the volume available for the expansion of the vapor and to prevent or reduce the injected coextractives from entering the analytical column, a ''retention gap'' is usually inserted between the injector and the column. A retention gap (or guard column) is a length of deactivated fused silica column without stationary phase, and thus without appreciable retention. Retention gaps of 1–5 m are used. About 30–40 cm of the retention gap are removed after a certain number of injections, depending on the type of matrix, extraction, and cleanup. Multiclass, multiresidue methods that use a minimal cleanup require more frequent cuttings.[15,21,25]

Injection liners are made of glass that is often deactivated by silanization. The inertness of the injection chamber can be monitored through the behavior of indicator compounds. For instance, appearance of DDE and DDD upon injection of DDT, and/or endrin aldehyde and endrin ketone upon injection of endrin, together with the shape of the peaks, is an indication of degradative activity. However, activity may be useful in certain cases. For instance, conversion of tralomethrin into deltamethrin in the injection chamber is part of the analytical method for the determination of

tralomethrin. As with packed columns, injection into hot vaporizing injectors introduces some degradation of the coextractives, which can lead to beneficial effects on the life of the column and quality of the chromatograms. Injection into cold injectors is preferable for heat-labile compounds, but often gives rise to more complex chromatograms.

When high sensitivity is desirable, large volumes of solvent can be injected with special techniques. In one approach, the injector can be kept at subambient temperature while repeatedly injecting the solution, or, with the "cryo focusing" technique, a short length of the column can be cooled to focus the analytes. In a special apparatus, the large volume of vapor generated by the injection is vented outside by activating an "early exit" valve during the concurrent evaporation of the solvent in the injector and retention gap.[83] Increasing the portion of the analytical sample injected allows a reduction in size of the aliquot of analysis and the analytical process, which is especially useful for instance when a large volume of water has to be extracted to attain low limits of determination.

Capillary columns are usually operated with helium as the carrier gas (less frequently hydrogen) since the optimum HETP (height equivalent theoretical plate) is maintained over a wide range of linear gas velocity. However, with conventional pressure- or flow-regulated systems, the change in flow rate due to column temperature programming is not taken into account, and the retention times and peak widths of low-volatility compounds increase. Most GC instruments now operate with electronic pressure control (EPC), which is a system able to maintain constant flow over the entire temperature program. This acts to reduce the analysis time and improve separation of compounds eluting at high temperatures, which is the case for some PYR pesticides. Pressure programming offered by EPC has been used to carry out pulsed splitless injection in conjunction with megabore columns. In this way, a high flow rate is used during injection to sweep the analytes out of the liner rapidly, thus reducing analyte loss due to adsorption or thermal degradation. This is useful for DDT/DDE, PYR, and polar OP pesticides. Also, pulsed splitless injection strongly reduces the chromatographic response enhancement caused by the so-called matrix effect.[7,159]

5.1.4 Selective Detectors

The great advantage of GC separation compared to other techniques in trace analysis in general and in pesticide residue analysis in particular is the availability of an array of simple-to-operate, sensitive, and selective detectors, such as the ECD, electroconductivity detector

Figure 1 GC/ECD chromatograms of *Scomber scombrus* fish. (a) 11.37 g + IS (internal standard) PCB 209, 0.06 µg, 1 µL injected, 1st fraction (*n*-hexane) of Florisil cleanup: 1, HCB, 0.4 µg kg^{-1}; 2, *p*,*p*′-DDE, 0.6 µg kg^{-1}; other peaks, PCB congeners, 0.28–12.45 µg kg^{-1}. (b) 11.37 g + IS PCB 209, 0.06 µg, 1 µL injected, 2nd fraction (*n*-hexane–benzene, 80 : 20 v/v) of Florisil cleanup: 1, γ-HCH, 0.96 µg kg^{-1}; 2, *p*,*p*′-TDE, 3.0 µg kg^{-1}; 3, *p*,*p*′-DDT, 0.42 µg kg^{-1}. (ElCD), halogen-specific detector (XSD), FPD, NPD, and chemiluminescent detector (CLD).[46,160]

The ECD is sensitive to compounds containing electron acceptor atoms or groups, such as halogen atoms, nitro groups, and unsaturated systems. OC pesticides by definition contain chlorine, while most PYR pesticides contain either chlorine, bromine, or fluorine. OC pesticides are usually analyzed by GC/ECD in a working range of 1–100 pg, while PYR pesticides are less sensitively measured in working ranges of 20–150 pg up to 50–500 pg, depending on the number and type of halogen in the molecules.[116,117] Figure 1 shows typical GC/ECD chromatograms of a fish extract (analyzed with acetone–*n*-hexane extraction, solid-matrix partition for separation of fat and cleanup by Florisil adsorption chromatography). Standard mixtures of OC pesticides are shown for comparison in Figure 2. Typical GC/ECD chromatograms of two soya oil samples spiked with two different standard mixtures of PYR pesticides together

with the corresponding standard mixtures are shown in Figures 3 and 4, respectively. For nonhalogen-containing pesticides, halogenated derivatives can be prepared to improve the detection with ECD.[95] A recent development is the nonradioactive ECD. Conventional ECD uses a ^{63}Ni foil as a source of electrons. In nonradioactive ECD, a pulsed discharge in pure helium generates high-energy photons that are used to photoionize a dopant gas added to the cell. The resulting electrons are used in the electron capture process. The pulsed discharge ECD offers several advantages over the ECD: (1) cleanliness, because the GC effluent does not come into contact with the ionization source; (2) linearity of four orders of magnitude; (3) sensitivity equal or better than the ECD; (4) low internal volume; and (5) elimination of the radioactive foil and associated safety measures.[161,162]

The ElCD (or Hall detector) is based on the catalytic reduction of halogen-containing compounds that produce hydrohalic acids which are detected and measured through the increase of electrolytic conductivity in a cell flushed by propanol. It is more selective than the ECD for halogens and is used for the analysis of halogen-containing PYR and OC pesticides.[25,46,104,105,111,163] Being halogen-selective, the ElCD is less sensitive to nonhalogen, electron-capturing interferences than the ECD. A number of fatty foods were analyzed for OC and PYR pesticides after SFE extraction and cleanup, without further cleanup.[164]

The XSD has been specifically developed for the selective detection of halogen-containing compounds in GC. Unlike the ElCD, the XSD does not require catalyst tubes, solvents, resin cartridges, a pump, or a transfer

Figure 4 GC/ECD chromatograms. (a) Standard mixture PYR-B, 1 µL injected. line. The XSD does not contain a radioactive source. The reactor is operated in an oxidative mode, which pyrolyzes the effluent from a GC column. This oxidative pyrolysis efficiently converts compounds containing halogen to their oxidation products and free halogen atoms. The cathodic surface is activated by neutralization of alkali ions emitted from the anodic surface. The adsorption and reaction of free chlorine atoms with this alkali-sensitized cathodic surface yields an increased thermionic emission comprised of free electrons and halogen ions. The total cathodic current is measured. XSD has a linear range of 10^4 and a selectivity Cl/HC $>10^4$.

The FPD, NPD, and CLD are element-selective detectors for compounds containing P or S, N and P, and N or S, respectively, but are not necessarily of interest in trace analysis for OC and PYR pesticides. Although some PYR contain N, they are not sensitively detected by N-selective detectors and interferences of N are greater than S or Cl. Endosulfan can be detected via S with pulsed FPD (PFPD) or CLD. The new PFPD is based on a pulsed flame and combustible gas flow rate that cannot sustain a continuous flame operation, and a pulsed emission of light is obtained. The pulsed flame operation shows some interesting features in pesticide residue analysis, including increased sensitivity for P- and S-containing compounds along with the possibility of distinguishing between the two signals and selectivity for other elements such as N, Sn, that are of interest in pesticide residue analysis.[165,166] The increased sensitivity for S would allow the detection of endosulfan and especially endosulfan sulfate. Indeed endosulfan sulfate, being more polar, usually occurs in dirtier fractions accompanied by more matrix interferences.

The coupling of a microwave-induced helium plasma atomic emission detector (AED) to GC has introduced multiple element selectivity for helping to identify organic chemicals in GC. Depending on the spectral lines selected, GC/AED can acquire signals for different elements in a single run. For example, Cl, Br, F, and N atoms for PYR and Cl for OC pesticides can be monitored.[167] This technique is less popular than GC/MS because of expense, reduced sensitivity and a lesser degree of confirmation.[168] AED has the potential in multiresidue analysis to detect compounds with metallic elements, for instance tin,[169] and to complement other element-selective detectors or MS. Indeed assembling a matrix of retention time parameters and responses to selective detectors is a common approach to identify compounds in screening samples for multiple pesticides in fruits and vegetables.[163,166,167]

5.1.5 Identification and Determination Procedures

For compounds analyzed by GC, tentative identification is based on matching the retention times or the relative retention times to those of standards. The minimum criterion for a tentative identification with selective detectors is the correspondence of the retention parameters on at least two columns of different polarity. Several compilations are available that give relative retention times on GC capillary columns of different polarity useful in multiclass, multiresidue analysis.[9–11,15,20,46,142] To reduce time for identification, GC instruments are often equipped with twin injectors (or a single injector connected to two columns with a Y-splitter) for simultaneous injection into two columns of different polarity connected to two ECDs,[44,142,155,156,170] or two different detectors, for instance an ECD and an ElCD in the determination of OC and PCB in foods and environmental samples.[105,171] In multiclass, multiresidue methods an ECD or an ElCD is combined with an NPD or an FPD.[46,54] The two chromatograms are acquired simultaneously. Cross matching the retention times helps the identification of the analytes.

Less frequently used is bidimensional GC in which a ''heart cut'' from the first column is transferred to a second column of different polarity.[7,156,172,173] Comprehensive orthogonal GC on two short columns of different polarity connected through a two-stage thermal desorption modulator has been applied to analyze OC pesticides from human serum in a few minutes with powerful separation capabilities.[156,174] In this case a complex bidimensional chromatogram is obtained that requires unconventional techniques for interpretation.

Further evidence for identification is provided by matching the analytical behavior through a combination of techniques based on different mechanisms of separation. Target compounds can be separated by adsorption TLC and transferred off-line to a gas chromatograph (matching R_f and retention time). Compounds separated by HPLC can be transferred to GC off-line or on-line. In on-line operation the peak of interest is trapped in a loop and by valve-switching transferred to a gas chromatograph equipped with a large-volume injection system. However these operations are useful for confirmation of target analyte(s) step by step.[175]

In GC- and HPLC-based techniques quantitation is usually carried out through peak area comparison with solutions of the standard compound at known concentration and either using a multilevel calibration curve, or interpolating between two standard solutions whose responses ''bracket'' the response of the sample (bracketing standards).[46] In some circumstances, single-point comparison is permissible.[37] The use of an IS is preferred to control final volume and injected volume variations. Not infrequently a ''matrix effect'' is observed in quantitation of pesticide residues at low levels. The matrix effect describes the difference of the response of the analytes injected in pure solvent (the usual ''solvent standards'') or mixed with the matrix components as they occur in the final extract (''matrix-matched standards''). Usually an increase in response is observed when the standard is injected with the matrix. Thus, if a sample component is quantitated against a standard in pure solvent, an overestimation of the component in the sample can often be observed. The matrix coextractives have a protective effect on the analyte during the injection and transfer into the column. The matrix effect depends on the nature of the compounds, and the performances of the GC injector. It is mostly apparent with polar, easily degradable compounds such as phosphoramides. Thus, the use of matrix-matched standards is recommended. The matrix effect has been observed with PYR,[125] and to a lesser extent with OC pesticides.[16,28,46,79,97,176] In a separate mechanism, in both GC- and HPLC-based quantitation the coelution of matrix components with the analyte, even if not detected by selective detectors, may alter the detector response. So, although certain analyses can be carried out with minimal cleanup, a more rigorous separation of matrix interferences may be beneficial from the quantitation and ruggedness points of view.

5.1.6 Gas Chromatography/Mass Spectrometry and Gas Chromatography/Fourier Transform Infrared Spectrometry

For on-line fast confirmation in multiresidue methods, GC takes advantage of the coupling to spectrometric identification techniques, such as MS and infrared (IR) spectrometry.

GC/MS is the most widely used technique for identification of organic GC-amenable compounds.[177] GC/MS is of paramount importance in analyzing PCB and toxaphene in environmental samples, and for the identification of metabolites and degradation products, for instance, of chlordane,[157] pentachloronitrobenzene,[178,179] and cypermethrin.[180] With modern benchtop GC/MS systems operating with capillary columns, the column is inserted directly into the ion source. Benchtop GC/MS instruments are based on either a quadrupole mass filter[20,29,46,90,134,163,168,181,182] or an ion trap detector (ITD).[69,97,99,115,183,184] The ITD also allows simple MS/MS operation, i.e. obtaining a mass spectrum from a previously formed fragment, that strongly increases the compound specificity of the technique.[185,186] Different ionization techniques are available, such as electron impact (EI) and chemical ionization (CI) in positive or negative mode. EI ionization mode gives extensive fragmentation that is characteristic of the molecular structure of the compound. Most frequently used is GC/EIMS, for which large electronic libraries of spectra are available that can be searched by appropriate software available on the data station. This search can often be carried out in combination with other parameters such as retention time and elemental information to restrict the number of candidate identifications.[166] Full spectra can be acquired with fractions of a nanogram, depending on the compound injected. Comparison of a full spectrum with the library spectrum and the spectrum of the authentic compound at the appropriate retention time gives almost unequivocal identification.

In selected ion monitoring (SIM) mode, also named multiple ion detection, MS is a sort of compound-selective detector tunable to different sets of ions. Decreasing the number of ions to be collected usually increases the sensitivity. Thus, SIM mode provides the highest sensitivity.

In multiresidue methods, for screening purposes the SIM mode is used, i.e. some diagnostic ions are followed in time windows appropriate to the detection of target compounds.[20,46,90,123,134,181,187] For reliable identification, the appearance of one to three ions at the correct

retention time and with the correct intensity ratios is considered necessary.[184] Several methods report a list of ions (m/z) that may be used to select diagnostic ions for SIM analysis.[15,16,17,20,46] However, a full EI spectrum should be obtained for unequivocal confirmation. In this respect the ITD is very sensitive in full scan mode and full scan spectra can be obtained with sub-nanogram amounts.

CI (more commonly with methane) gives less fragmentation than the EI mode and spectra with only a few ions are recorded, with $M+1$ or $M+CH_4$ being normally the most abundant in positive CI. The lesser fragmentation results in increased sensitivity. Although less definitive than the EI spectrum, the CI spectrum together with retention time data provides sufficient evidence for the presence of an analyte.[69,184] Negative ion CIMS takes advantage of the electronegative character of polychlorinated compounds. Negative ion CIMS has been used to detect PCB and OC pesticides with high sensitivity in plant materials,[29] human blood,[182] and the environment.[156] Negative ion CIMS with methane has also been used for the determination of four PYR in soil,[134] and offers sensitivity of the same order of GC/ECD.[153]

High-resolution MS is used as the ultimate identification technique at very low levels in food,[46] and in environmental studies.[71,156]

The gas chromatograph coupled to a Fourier transform infrared (FTIR) spectrometer is also a powerful identification technique but has not achieved widespread routine application in pesticide residue analysis.[188]

5.2 High-performance Liquid Chromatography

With the development of high-performance columns and sensitive detectors the applications of HPLC to residues analysis are paralleling the GC applications. HPLC is primarily suited to the analysis of polar, low-volatility, and thermally labile compounds. This is particularly the case for the new classes of pesticides having more complex structures and increasing molecular weight. A limitation of HPLC compared to GC is the fewer types of detectors. Traditionally, the variable-wavelength ultraviolet/visible (UV/VIS) detector usually operated in the 200–350 nm range and the fluorescence detector are the main choices. Most OC pesticides are poorly detected by either technique and for them HPLC has been used mainly as a separative cleanup, as mentioned previously. PYR can be analyzed at residue level by the UV detector.[32,38,138,139] Particularly for nonhalogen-containing PYR, such as allethrin, fenpropathrin, phenothrin, resmethrin, and tetramethrin, HPLC can provide the only determinative technique at residue level apart from GC/MS.[153] Reverse-phase chromatography either on octyl-silica (C_8) or octadecyl-silica (C_{18}) is the most popular separation mechanism, where low polarity compounds, such OC and PYR pesticides, are strongly retained, while more polar compounds elute earlier.

Fluorescence detection is useful for naturally fluorescent compounds or compounds that can be derivatized to fluorescent compounds. HPLC with fluorescence detection has been used for the determination of residues of piperonyl butoxide, a synergist used in PYR formulations, in rice, grains, and beans.[153]

The analysis of single enantiomers is important not only to characterize the formulated products, but also for appropriate assignment of the MRL value in residue analysis.[153] Chiral phases are available as HPLC columns that permit the separation of some of these enantiomers.[153,189]

As in GC, HPLC coupled to spectral techniques is necessary for a reliable identification at trace levels. Fast scanning or photodiode array (PDA) spectrophotometers allow the identification of compounds by retention time and spectrum comparison with authentic compounds under the same conditions. HPLC with PDA instrumentation has become common in the residue laboratory.

HPLC, especially with minibore columns, can be coupled to GC. Selected peaks from HPLC can be transferred to GC by valve switching technology and large-volume injection systems. HPLC/GC can, thus, take advantage of the sensitivity and selectivity of the array of detectors developed for GC, including GC/MS, and GC takes advantage of the selectivity options offered by liquid chromatography. Thus, the identification can be supported by two mechanisms of separation and a spectral technique.[175]

After years of continuous developments and improvements, HPLC/MS coupling has almost reached the simplicity and reliability of GC/MS, at least for benchtop, quadrupole or ion trap mass analyzers. Nowadays the most used interfaces are electrospray and atmospheric pressure CI. Thus, mass spectral confirmation can be obtained also for polar, heat-labile, low volatility, high molecular weight compounds, which include PYR and other new pesticides. HPLC/MS gives CI-type mass spectra which typically have peaks for structural elucidation or confirmation purposes. Both positive and negative ion extraction mode is possible. The choice between positive and negative ion mode depends on the compounds to be analyzed. In the positive ion mode the base peaks are normally the protonated forms of the compounds or their adducts with the cations used in the HPLC eluent. The negative ion mode is more sensitive for electronegative compounds and the base peaks are normally the adducts with the

anions used in the eluent buffer. Also, apparatus is available for HPLC/MS that can perform the MS/MS operation.[190–193]

5.3 Thin-layer Chromatography

Adsorption TLC on alumina has been used for OC pesticides.[8] The eluting solvent was *n*-hexane or its mixtures with a small amount of polar modifiers, such as DCM or acetone. Detection of OC pesticides on the plates was carried out by spraying a chromogenic reagent (a solution of silver nitrate in 2-phenoxyethanol–acetone) and exposing the plate to UV light. Quantities as low as 5 ng of most OC pesticides can be detected. Separation and identification on silica gel plates have been reported.[194,195] Although almost superseded by other techniques, in pesticide residue analysis TLC is gaining a renewed interest after the introduction of high-performance thin-layer chromatography (HPTLC) plates and automated multiple development (AMD) with inverse gradient elution, especially in the analysis of environmental samples.[196–198] Very small bands with reproducible R_f are obtained so that the separation of a large number of compounds in a single run is possible. Identification can be obtained through comparison of R_f and UV or fluorescence spectra acquired with spectrophotometric scanners. The quantitation is possible at very low levels and is carried out by peak areas comparison in multiple-wavelength scanning.

Micro liquid chromatography can be coupled to HPTLC by nitrogen-assisted spraying of different portions of the HPLC eluent onto different lanes of the HPTLC plate. Afterward the plate is developed with the AMD mode and each lane is scanned for peak identification and quantitation. HPLC/HPTLC is a powerful identification tool which combines the high resolution power of HPLC and HPTLC with two different mechanisms of separation (for instance reverse-phase HPLC and adsorption TLC) in an orthogonal high peak capacity separation system, particularly suited for polar heat-labile compounds.[198]

ABBREVIATIONS AND ACRONYMS

AED	Atomic Emission Detector
AMD	Automated Multiple Development
CI	Chemical Ionization
CLD	Chemiluminescent Detector
DCBP	Dichlorobenzophenone
DCM	Dichloromethane
DDA	Di(*p*-chlorophenyl)acetic Acid
DDD	Dichlorodiphenyldichloroethane
DDE	Dichlorodiphenyldichloroethylene
DDT	Dichlorodiphenyltrichloroethane
DMF	Dimethylformamide
DMSO	Dimethyl Sulfoxide
DVB	Divinylbenzene
ECD	Electron Capture Detector
EI	Electron Impact
ElCD	Electroconductivity Detector
EPC	Electronic Pressure Control
FPD	Flame Photometric Detector
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
HCB	Hexachlorobenzene
HCH	Hexachlorocyclohexane
HEPO	Heptachlor Epoxide
HETP	Height Equivalent Theoretical Plate
HPLC	High-performance Liquid Chromatography
HPSEC	High-performance Size-exclusion Chromatography
HPTLC	High-performance Thin-layer Chromatography
IR	Infrared
IS	Internal Standard
ITD	Ion Trap Detector
LLE	Liquid–Liquid Extraction
LLP	Liquid–Liquid Partitioning
MAE	Microwave-assisted Extraction
MRL	Maximum Residue Level
MS	Mass Spectrometry
MSPD	Matrix Solid-phase Dispersion
NPD	Nitrogen–Phosphorus Detector
NPHPLC	Normal Phase High-performance Liquid Chromatography
OC	Organochlorine
OP	Organophosphorus
PCB	Polychlorinated Biphenyl
PDA	Photodiode Array
PFPD	Pulsed FPD
PLE	Pressurized Liquid Extraction
PSA	Propylethylenediamine – Silica
PS–DVB	Polystyrene–Divinylbenzene
PYR	Pyrethroids
R_f	Retention Factor
SAX	Strong Anion Exchanger
SEC	Size-exclusion Chromatography
SFE	Supercritical Fluid Extraction
SIM	Selected Ion Monitoring
SPE	Solid-phase Extraction
SPME	Solid-phase Microextraction
TLC	Thin-layer Chromatography
UV	Ultraviolet
UV/VIS	Ultraviolet/Visible
XSD	Halogen-specific Detector

RELATED ARTICLES

Environment: Trace Gas Monitoring **(Volume 3)**
Laser Mass Spectrometry in Trace Analysis

Environment: Water and Waste **(Volume 3)**
Capillary Electrophoresis Coupled to Inductively Coupled Plasma-Mass Spectrometry for Elemental Speciation Analysis • Detection and Quantification of Environmental Pollutants • Dioxin-like Compounds, Screening Assays • Gas Chromatography with Atomic Emission Detection in Environmental Analysis • Gas Chromatography with Selective Detectors for Amines • Industrial Waste Dumps, Sampling and Analysis • Infrared Spectroscopy in Environmental Analysis

Environment: Water and Waste cont'd **(Volume 4)**
Liquid Chromatography/Mass Spectrometry in Environmental Analysis • Microwave-assisted Techniques for Sample Preparation in Organic Environmental Analysis • Microwave-enhanced Solvent Extraction of Organics in Environmental Analysis • Organic Analysis in Environmental Samples by Capillary Electrophoresis • Polychlorinated Biphenyls Analysis in Environmental Samples • Sample Preparation for Environmental Analysis in Solids (Soils, Sediments, and Sludges) • Sampling Considerations for Biomonitoring • Solid-phase Microextraction in Environmental Analysis • Soxhlet and Ultrasonic Extraction of Organics in Solids • Supercritical Fluid Extraction of Organics in Environmental Analysis • Trace Organic Analysis by Gas Chromatography with Quadrupole Mass Spectrometry • Trace Organic Analysis by Gas Chromatography with Selective Detectors

Field-portable Instrumentation **(Volume 5)**
Solid-phase Microextraction in Analysis of Pollutants in the Field

Food **(Volume 5)**
Infrared Spectroscopy, Gas Chromatography/Infrared in Food Analysis • Liquid Chromatography in Food Analysis • Pesticides, Mycotoxins and Residues Analysis in Food • Sample Preparation Analytical Techniques for Food • Sample Preparation for Food Analysis, General • Sample Preparation, Headspace Techniques

Pesticides **(Volume 7)**
Pesticide Analysis: Introduction • Biological Matrices: Pesticides Content Sampling, Sample Preparation and Preservation • Carbamate and Carbamoyloxime Insecticides: Single-class, Multiresidue Analysis of • Gas Chromatography and Supercritical Fluid Chromatography with Selective Detection in Pesticide Analysis • Gas Chromatography/Mass Spectrometry Methods in Pesticide Analysis • Herbicide Residues in Biota, Analysis of • Herbicides (New Generation): Imidazolinones, Aryloxyphenoxypropionic Acids/esters, and Diphenylethers, Analysis of • High-performance Liquid Chromatography Methods in Pesticide Residue Analysis • High-performance Liquid Chromatography/Mass Spectrometry Methods in Pesticide Analysis • Immunochemical Assays in Pesticide Analysis • Multiclass, Multiresidue Analysis of Pesticides, Strategies for • Organophosphorus Pesticides in Water and Food, Analysis of • Pesticides (New Generation) and Related Compounds, Analysis of • Pesticides in Water: Sampling, Sample Preparation, Preservation • Phenoxy Acid and Other Acidic Pesticides: Single Class, Multiresidue Analysis of • Phenyl- and Sulfonylurea Herbicides: Single Class, Multiresidue Analysis of

Pesticides cont'd **(Volume 8)**
Soil and Sediments: Pesticides Content Sampling, Sample Preparation, and Preservation • *s*-Triazine Herbicides and their Transformation Products, Multi-residue Analysis of

Gas Chromatography **(Volume 12)**
Gas Chromatography: Introduction • Column Technology in Gas Chromatography • Data Reduction in Gas Chromatography • Hyphenated Gas Chromatography • Instrumentation of Gas Chromatography • Liquid Phases for Gas Chromatography • Multidimensional Gas Chromatography • Sample Preparation for Gas Chromatography

Infrared Spectroscopy **(Volume 12)**
Gas Chromatography/Infrared Spectroscopy • Liquid Chromatography/Infrared Spectroscopy

Liquid Chromatography **(Volume 13)**
Chiral Separations by High-performance Liquid Chromatography • Normal-phase Liquid Chromatography • Reversed Phase Liquid Chromatography • Supercritical Fluid Chromatography • Thin-layer Chromatography

Mass Spectrometry **(Volume 13)**
Mass Spectrometry: Overview and History • Atmospheric Pressure Ionization Mass Spectrometry • Chemical Ionization Mass Spectrometry: Theory and Applications • Electron Ionization Mass Spectrometry • Gas Chromatography/Mass Spectrometry • High-resolution Mass Spectrometry and its Applications • Liquid Chromatography/Mass Spectrometry • Literature of Mass Spectrometry • Quadrupole Ion Trap Mass Spectrometer • Tandem Mass Spectrometry: Fundamentals and Instrumentation

Organophosphorus Pesticides in Water and Food, Analysis of

Sílvia Lacorte and Damià Barceló
CID–CSIC, Barcelona, Spain

1 Introduction 1
1.1 Sources and Uses of Organophosphorus Pesticides 1
1.2 Distribution and Fate of Pesticides 2
1.3 Physical and Chemical Properties 2
1.4 Regulations 4
2 Outline of the Analytical Method 5
3 Water Sample Handling 6
3.1 Liquid–Liquid Extraction 6
3.2 Solid-phase Extraction 6
3.3 Types of Sorbent Materials 9
3.4 Parameters Involved in Solid-phase Extraction 10
4 Collection and Preparation of Food Samples 11
4.1 Collection of Food Samples 11
4.2 Analytical Preparation of Food Samples 11
5 Gas Chromatographic Determination 13
5.1 Gas Chromatographic Detectors 13
5.2 Gas Chromatography/Mass Spectrometry with Electron Ionization 13
5.3 Gas Chromatography/Mass Spectrometry with Chemical Ionization 14
6 High-performance Liquid Chromatography 15

The purpose of this article is to provide an overview of the main characteristics of organophosphorus pesticides (OPPs), such as their physicochemical characteristics, sources, fate and distribution in the environment. It covers regulatory compliance from the Commission of the European Communities (CEC) and the United States National Pesticide Survey (USNPS), regarding the maximum permissible levels of the most toxic and persistent OPPs and their transformation products (TPs) in water. This article also describes the analytical methods currently used to monitor pesticides and their degradation products in water and food matrices. A major part concerns sample preparation techniques and includes traditional liquid–liquid extraction (LLE) and novel techniques based in automated solid-phase extraction (SPE), either on-line or off-line. New sorbent materials, their applications and the parameters involved in the extraction are described. Chromatographic methods used for their determination are discussed in detail. Much emphasis has been given to gas chromatography (GC) and liquid chromatography (LC) coupled to mass spectrometry (MS) as a confirmation technique and mass spectral information on several pesticides has been included. The final section is devoted to method validation, with the aim of providing a basis and a framework of information for quality assurance (QA) and interlaboratory calibration studies.

1 INTRODUCTION

1.1 Sources and Uses of Organophosphorus Pesticides

Much concern is being given to the determination of pesticides in the different environmental matrices, owing to the increased number of pesticides detected and to the severe rules imposed by legislation aimed at protecting natural resources.[1,2] OPPs were introduced on to the market in the period 1945–55, to replace the toxic and persistent organochlorine insecticides, mainly DDT. They represent a family of about 140 different compounds, which are classified in different groups depending on their chemical structure. They are esters, amides or thiols which in general derive from phosphoric or phosphonic acid, where one or more atoms of hydrogen are substituted by organic groups. Depending on the functional groups, OPPs are divided into six groups or families: phosphates, phosphonates, phosphorothionates, phosphorodithioates, phosphorothiolate and phosphoroamidate. Table 1 summarizes the chemical structure

Table 1 Chemical structures of different families (groups) of OPPs

Group	Structure[a]	Examples
Phosphate	$(R{-}O)_2\overset{\overset{O}{\|}}{P}{-}O{-}X$	Chlorfenvinfos, dichlorvos, mevinphos
Phosphonate	$(R{-}O)_2\overset{\overset{O}{\|}}{P}{-}H{-}X$	Trichlorfon
Phosphorothioate	$(R{-}O)_2\overset{\overset{S}{\|}}{P}{-}O{-}X$	Chlorpirifos, coumaphos, diazinon, fenitrothion, fenthion, parathion, temephos
Phosphorothiolate	$(R{-}O)_2\overset{\overset{O}{\|}}{P}{-}S{-}X$	Demeton-*S*-methyl
Phosphorodithioate	$(R{-}O)_2\overset{\overset{S}{\|}}{P}{-}S{-}X$	Azinphos, disulfoton, malathion, fosmet
Phosphoramidate	$X/R{-}O{-}\overset{\overset{O}{\|}}{P}{-}NH{-}R$	Fenamiphos

[a] R = alkyl or aryl groups; X = aliphatic, aromatic or heterocyclic groups.

of each group. Because the P=S bond is the most stable, many OPPs are synthesized with such a configuration. The characteristics of each group of OPPs can vary substantially, and they confer the specificity to react against one type of organism or another. In general terms, the mode of action of OPPs is based on the inhibition of the enzyme acetylcholine esterase of the organisms, which blocks the nervous transmission and produces death normally by respiratory depression. Owing to this specificity and because they are rapidly degraded after application and are rarely accumulated in the trophic chain, OPPs are extensively used to combat different pests. The main uses are in agricultural crop production, industrial activities and in the tertiary sector (domestic use, mosquito and rodent control, greenhouses, cemeteries, aquaculture, golf courses, etc.). In such practices, OPPs are applied as formulations to enhance their effectiveness upon application, absorption, translocation, immobilization and detoxification. Formulations contain additives and adjuvants such as mixtures of surfactants, mineral and vegetable oils, emulsifiers and salts.

1.2 Distribution and Fate of Pesticides

The distribution and fate of pesticides in the environment depends on whether the pesticide is locally applied or is thoroughly spread over large crop field extensions. Local applications are normally performed by manual spraying or from tractor-trailers, and represent the utmost controlled and optimal conditions since only target organisms are eliminated and pesticide spreading and dissipation are limited. Helicopters or aeroplanes are used to spray large extensions, and dispersion and especially volatilization often occur; as a consequence, pesticides can be found in the atmosphere and in areas far away from the focus treatment point. Once the pesticides have been introduced onto the water or soil surface, they can be transported from the point-source by drift, runoff or soil migration. Moreover, their concentration starts to decrease as a consequence of dispersion, volatilization, degradation and lixivation, among others. The importance of each process greatly depends on the physicochemical properties of each compound, and also on the water and soil properties, the environmental conditions and the applied concentration and mode of application. During the time a pesticide remains in the environment, chemical (mainly photolysis and hydrolysis) and biological degradation can occur, with the subsequent formation of a TP[3] such as oxo derivatives, sulfones and sulfoxides. Moreover, chloro- and nitrophenols have been reported as the main degradation products of many OPPs.[4,5] Parent pesticides can remain in the soil or sediment whereas TPs, which are more polar than the parent compounds, have a higher capacity to lixiviate and migrate through soil and sediment. As a result, TPs have been encountered in places far away from the point of application and contaminating groundwaters.[6] Groundwater pollution represents a serious environmental problem since in many places these waters are used for drinking and irrigation purposes. In addition, it is known that many TPs are more toxic than their parent compounds[7] so that they can produce deleterious effects towards flora and fauna of surface and groundwaters and in sediment organisms.

It is impossible to define a unique fate of pesticides and TPs in the environment since distribution, transport, degradation, dispersion, soil retention and lixiviation will depend on the environmental conditions and on the physicochemical properties of each pesticide. Hence it is clear that to assess the environmental impact of pesticides and their TPs, one should consider all environmental matrices (surface waters, groundwater, soil, vegetables and fruits, atmosphere, etc.). The following section is intended to summarize the most important physicochemical parameters of OPPs and the role they play under environmental conditions.

1.3 Physical and Chemical Properties

OPPs have characteristic chemical structures which confer different physicochemical properties. For instance,

polarity, water solubility, vapor pressure, water–octanol partition coefficient, half-life and acid–base ionization are the main aspects that will influence the persistence or degradation of each OPP in the environment. These physicochemical parameters are generally measured under controlled laboratory conditions, and under similar conditions comparable values are obtained in the literature. Some of these parameters, such as half-life or Ground ubiquity score (mobility index) (GUS), to mention the most important, depend considerably on the specific conditions set up for the experiment and can be measured under either laboratory or environmental conditions. Experiments performed under environmental conditions provide very realistic data which permit one to determine the main degradation processes that occur in natural conditions. However, since they are affected by the temperature, humidity, soil characteristics, water pH, etc., very disparate data are obtained from different authors. *The Pesticide Manual*[8] and a book on trace determination of pesticides in water[9] list several physicochemical parameters of OPPs. In evaluating the behavior of pesticides in the environment, one should consider the physicochemical properties of each specific pesticide with the objective of establishing the main pathways of the pesticides and the routes of degradation. On the other hand, knowledge of the physicochemical properties of each compound is useful in defining the analytical method for its determination.

Water solubility, defined as the concentration of a chemical dissolved in water, is a parameter that both affects the extraction of pesticides from water, food and soil samples and influences the fate of pesticides in the environment. The water solubilities of OPPs are very variable, with compounds which are almost completely soluble, such as mevinphos ($600\,g\,L^{-1}$), and others which are totally insoluble, such as temephos ($0.00003\,g\,L^{-1}$). In general, distant water solubilities affect the extraction procedure, since the most soluble ones (water solubilities above the grams per liter level) will be difficult to trap and the most insoluble (water solubilities lower than $0.5–1\,mg\,L^{-1}$) will easily remain adsorbed upon the glassware and other laboratory material, which leads to lower recovery values.

After application of an OPP, this parameter is essential for determining whether a specific compound will remain dissolved in water, is a potential leacher, will be adsorbed on sediment particles or will precipitate at the surface soil. In general terms, it gives a clue to the distribution of a pesticide in the environment. However, this parameter cannot be used solely to predict the distribution of OPPs in the environment.

A parameter related to the water solubility is the water–octanol partition coefficient (reported as a logarithm, usually $\log K_{ow}$ or $\log P_{ow}$), which is an indicator of the degree of hydrophobicity of a pesticide and its tendency to accumulate in living cells or organisms or to be adsorbed on the organic matter of soils and sediments (humic and fulvic substances). As a rule of thumb, pesticides are classified as apolar if $\log K_{ow}$ values are above 4–5 and polar if they are below 1.5. Between these values, they are considered as ''moderately polar''. OPPs with a high $\log K_{ow}$ value (above 4) have a high bioaccumulation potential and therefore they are compounds that if applied at high concentrations can be transferred along the trophic chain. In addition, the soil organic carbon sorption coefficient (K_{oc}), expressed as $cm^3\,g^{-1}$, is used as an indicator of the degree of attraction and retention of the pesticides in the particles of the soil. The retention will basically depend on the type of soil, and will affect the behavior of the OPP in the field, since an adsorbed molecule can be difficult to solubilize by water, and its availability will decrease. This parameter will also indicate the leaching potential of a pesticide. In general, pesticides with K_{oc} values below 50 are highly mobile, values between 150 and 500 represent moderately mobile compounds and values higher than 2000 are slightly mobile compounds. The K_{oc} values of OPPs are very variable, and vary from 44 for mevinphos to 498 for chlorpyriphos.

The solubility, mobility and volatilization of OPPs in the environment will largely depend on their acid–base ionization constants (pK_a) and whether they are ionized at the pH of each compartment. Volatilization depends on the vapor pressure of each pesticide and on the climatic conditions where the pesticide has been applied, mainly the ambient temperature. OPPs are medium-volatility compounds, with vapor pressures which vary between 0.13 and 7000 mPa. The most volatile compounds will be lost to the atmosphere, especially during application. However, once the OPPs have settled upon the aquatic medium, volatilization will depend on their solubility in water. The Henry's law constant, denoted H or K_H (expressed in $Pa\,m^3\,mol^{-1}$), is defined as the coefficient between the vapor pressure of a pesticide and its solubility in water, and indicates the volatilization of a compound in solution. To give an example, chlorpyrifos, with a low water solubility ($0.0014\,g\,L^{-1}$) will be easily lost to the atmosphere. It is generally accepted that compounds with H values below $10^{-5}\,Pa\,m^3\,mol^{-1}$ will have little tendency to volatilize.

A common way to evaluate the persistence of a pesticides in the environment is the half-life ($t_{1/2}$). The half-life is defined as the time required for a pesticide to reduce the initial concentration by 50%, and it is calculated from the first-order Equation (1):

$$t_{1/2} = \frac{\ln 2}{k} \tag{1}$$

where k is the time constant. Half-lives can be calculated under controlled laboratory conditions using Milli-Q water and artificial radiation, simulating environmental conditions,[10] or under real environmental conditions. The last case represents the most realistic approach since many different factors and processes play a role in pesticide degradation and dissipation.[6,11] Generally, one takes advantage of phytosanitary treatments to calculate the half-life of a pesticide after it has been applied. The half-lives of OPPs in the environment vary from a few hours to several days, but this value depends on the intrinsic characteristics of each pesticide and on the experimental conditions (climatic conditions, microbial activity, soil and water type, etc.).

Another parameter of environmental interest is the mobility index or GUS, which provides a leaching classification depending on the soil half-life and the K_{oc} value Equation (2):

$$\mathrm{GUS} = \log T_{0.5}(4 - \log K_{oc}) \qquad (2)$$

where $T_{0.5}$ is the soil half-life of the pesticide. A GUS higher than 2.8 indicates that the pesticide can be considered as a leacher. Values lower than 1.8 indicate nonleacher pesticides.

In general terms, it can be concluded that the stability of OPPs in the environment depend on several parameters, many of them correlated, in such a way that it is difficult to define a unique parameter as responsible for the fate of OPPs in the environment.

1.4 Regulations

Nowadays, hundreds of different OPPs are being used for different purposes. Since 1970, authorities have started to appreciate the danger of water pollution and the need to check the water quality to protect natural drinking sources. Strict directives have been set up and monitoring the concentration levels of OPPs and their TPs in water and other environmental matrices is compulsory. The European Union (EU) has elaborated a ''Black List'' which includes the 132 most toxic substances for the environment.[12] Among other families of compounds, 21 toxic, persistent and widely used OPPs are included. These are designated as priority OPPs and are listed in Table 2. Effort is directed at determining these compounds in monitoring programs.

Moreover, the EU Directive on the Quality of Water Intended for Human Consumption (CEC 76/464/EEC) has elucidated maximum permissible levels of pesticides in drinking water which should be below $0.1\,\mu g\,L^{-1}$ for each individual pesticide and that the sum of all pesticides should be below $0.5\,\mu g\,L^{-1}$.[2] In surface water, the concentration of pesticides should be between 1 and $10\,\mu g\,L^{-1}$. Moreover, the USNPS has published a list which includes all pesticides and their TPs, mainly sulfoxides, sulfones and oxo derivatives of OPPs, which were detected in US groundwaters and are considered polar, toxic and persistent.[13,14] An overview on the use, consumption and regulatory activities and actions of both the EU and USNPS has been described by Barceló.[15] Furthermore, a recent EU Directive appeared in 1996[16] that expands the number of contaminants to be monitored in surface and waste effluent waters. The objective is to determine the potential toxicity and environmental impact of newly identified substances (e.g. TPs of pesticides and very polar compounds, which are difficult to analyze using conventional techniques). As a result, most countries control the levels of pesticides in different types of waters with the aim of providing ways and solutions to reduce the level of pollutants in surface and groundwaters. To accomplish such a purpose, it is necessary to use analytical methods which permit the

unequivocal identification and confirmation of pesticides along with their TPs in the environment in a quick and reliable way.

This article describes first the different techniques used for the extraction of pesticides in water and food samples, showing the advantages and disadvantages of each, and discussing the parameters which influence the extraction step. Subsequently, an overview of the most common detection techniques used for OPPs is given. This will permit one to evaluate which is the preferred technique according to the chemical nature of each compound, in which cases it can be used and the information that one will gather. The final section consists of a review of the different validation steps that have to be performed to evaluate any analytical technique. This is specially relevant since all techniques have to be validated for qualitative parameters before they can be routinely applied for monitoring purposes.

2 OUTLINE OF THE ANALYTICAL METHOD

In general terms, determinations of OPPs include four main steps: (i) sampling, (ii) extraction and cleanup of the analytes from the sample, (iii) concentration of the analytes and (iv) detection. The sampling step has to be performed so that the sample is a representative part of a whole area, recovery is maximized and sample contamination is avoided. Barceló and Hennion[17] have reviewed different sampling strategies, which depend on the type of water to be analyzed and on the sample location.

Many different extraction procedures have been described to isolate pesticides from water. Dichloromethane LLE methods have been reported in the literature, covering several groups of pesticides and being also recommended by the United States Environmental Protection Agency (USEPA) through its National Pesticide Survey.[18,19] As an alternative to LLE, SPE procedures, also known as liquid–solid extraction (LSE), have been implemented in the last few years, and can be performed both off-line and on-line. SPE methods can be easily converted into fully automated on-line systems coupled to high-performance liquid chromatography (HPLC), in brief LC or GC. Such systems, also referred to as precolumn technology, show additional advantages such as lower detection limits (DLs) (for a given amount of water volume preconcentrated) and that sample manipulation is minimized, which is translated to no evaporation losses, no contamination, no need to concentrate the sample, easy automation and use of small amounts of toxic solvents. There is a great availability of sorbents and configurations which permit the efficient trapping of compounds of diverse polarities with the percolation of only 50–100 mL of water. Recently, besides the well-known C_{18} and polymeric sorbents, immunoaffinity precolumns have appeared as an alternative to preconcentrate selectively the analytes of interest.[20] To isolate pesticides from food samples, Soxhlet extraction followed by a cleanup step is the most common approach.

As regards to the analysis of pesticides belonging to different classes, the traditional detection technique has been GC using a selective detector such as the nitrogen-phosphorus detector (NPD)[21] or flame photometric detection (FPD),[22] among others. Classically, identification of the analytes is done through retention time comparison with a standard solution. Errors and lack of reproducibility can often appear owing to variations in the response of the detector and to retention time shifts. This is specially relevant when GC/NPD or gas chromatography/flame ionization detection (GC/FID) is used, and therefore duplicate analysis using two columns of different polarity, or otherwise the addition of internal standards (added at the beginning of the analysis) or surrogates (preferably a labeled standard added prior to injection), is needed in order to meet quality control (QC) requirements.[19] The use of GC with MS detection is a valid alternative to confirm the results obtained by other techniques. However, GC-based techniques are not suitable for the analysis of polar, non-volatile and thermolabile compounds, since for these compounds a derivatization step prior to GC analysis is compulsory. The use of two different detection techniques (or the more expensive MS detector) and the inability to analyze both the polar TPs along with the parental pesticides limit the applicability of GC-based techniques for OPPs' analysis.

LC techniques are preferred for the analysis of organic pollutants since they cover a wide range of polarities and permit the identification of pesticides along with their TPs. Liquid chromatography with diode-array detection (LC/DAD) has successfully been used to monitor OPPs.[23] The main advantage of LC/DAD is related to its easy use and to the fact that it offers an absorbance spectra that can be used to identify pesticides through spectral comparison. However, limitations arise for nonultraviolet (UV)-absorbing compounds and because of the impossibility of identifying unknown pesticides (e.g. TPs) in real water samples. Moreover, typical problems related to the analysis of surface waters with LC/DAD are the co-elution of two or more compounds and the presence of interferences, mainly due to humic and fulvic material. To overcome these problems, liquid chromatography with mass spectrometric detection (LC/MS) is used. The higher selectivity and the possibility of obtaining spectral information, together with sufficient sensitivity to use it for quantification purposes, are the main advantages

of this technique. LC/MS with a thermospray (TSP) interface[24–26] has probably been the most widely used technique for pesticide monitoring. In general, it produces molecular information and scarce fragmentation. More structural information can be obtained by using filament-on or discharge ionization. LC/MS with a particle beam (PB) interface[27] has also been extensively applied since it offers abundant fragmentation and can be compared with electron ionization (EI) mass spectra. The high DLs and poor reproducibility are the main problems related to this technique. The advent of atmospheric pressure ionization (API) LC/MS interfaces has overcome the disadvantages of GC/MS and other LC/MS interfacing devices such as TSP, because they can provide structural information similar to chemical ionization (CI) and very good sensitivity. Electrospray (ESP), ionspray (ISP) and atmospheric pressure chemical ionization (APCI) have been applied for pesticide monitoring[28–30] and a DL of few nanograms per liter and a linear response range over two orders of magnitude have been reported.

3 WATER SAMPLE HANDLING

After application, pesticides are generally found in the environment at low concentrations, generally around parts per billion or trillion (ppb–ppt level respectively). The trace analysis of pesticides in drinking, surface and wastewaters require the preconcentration of pesticides from the water matrix prior to the chromatographic analysis. The preconcentration step, also referred to as sample pretreatment, involves not only the extraction of pesticides from the water matrix but also the isolation or sample cleanup and generally account for the major part of sample analysis. Traditionally the preconcentration of pesticides was carried out by LLE but nowadays there is a general trend to change to SPE procedures. Both approaches will be discussed below.

3.1 Liquid–Liquid Extraction

LLE is in many cases the sample preparation technique preferred by the environmental analyst because of its extensive implementation in official methods. LLE is based on the partitioning of different components between aqueous solution and an immiscible organic solvent. Most of the current USEPA methodologies for the analysis of priority pollutants, including pesticides, in water samples involve extraction with various solvents such as dichloromethane, either in acidic conditions to avoid hydrolysis of pesticides[31] or at neutral pH,[32] with butyl acetate,[33] chloroform[34] and hexane.[35] Other approaches have been described using ion pair-forming agents by adjusting the pH to a basic value and adding quaternary ammonium salts.[36] The selectivity of LLE depends on the solvent used, extraction pH, ionic strength, water to solvent ratio, number of extractions and the chemical nature and concentration of the analytes. However, LLE has some drawbacks, e.g. it requires large amounts of generally toxic and inflammable organic solvents, emulsions can be generated and further cleanup is often necessary. The procedure is tedious and it involves considerable sample manipulation, which may lead to losses during the concentration step and result in many cases in poor recoveries and bad reproducibility, with the risk of sample contamination. In addition, evaporative losses may occur during removal of the large solvent volumes, thus making the analysis inaccurate and scarcely reproducible. Moreover, its automation requires the use of expensive robots. Hence there is a general trend to change current LLE procedures to SPE protocols.

3.2 Solid-phase Extraction

SPE has been successfully applied to extract and store pesticides from environmental water matrices and as a cleanup procedure for sediments and food samples.[37] The procedure is based on the use of an adsorbent material which is capable of selectively retaining the pesticides from the matrix. Briefly, the mode of action consists in percolating the sample through the sorbent where the pesticides are retained; subsequently, the pesticides are selectively eluted with an organic solvent. Nowadays there exist a wide variety of SPE methods, which may be divided into off-line and on-line (or precolumn technology) methods. The chemistry and principles of these two approaches are identical. The method involves different steps: (i) washing the sorbent with an organic solvent, often the same solvent as will be used for the elution step; (ii) activation of the sorbent (wetting) with a water-miscible solvent (normally methanol or acetonitrile); (iii) removal of the excess of solvent with pure water; (iv) percolation of the water sample; (v) removal of interferences (cleanup) by flowing water or solvent through the sorbent bed at a high flow rate; and (vi) elution of trapped analytes with a selective solvent, normally compatible with further chromatographic detection system. The different SPE procedures will be described in detail.

3.2.1 Off-line Solid-phase Extraction Methods

In off-line SPE methods, the water sample is percolated through the sorbent bed which is packed in a disposable cartridge or enmeshed in a membrane extraction disk. Samples can move through the sorbent bed by gravity or by application of a positive (syringe) or negative (vacuum manifold) pressure. In general, off-line practices

are well accepted owing to the large variety of packing materials available, C_8, C_{18}, polymeric phases and graphitized carbon black (GCB) being the most common, with different sizes and volumes, which allows great operational flexibility. In the cartridge format, 30 mg–2 g or more of sorbent (normally of 40–150-μm particle size) are usually packed in a polypropylene, Teflon or glass syringe to avoid sample contamination. The off-line procedure using cartridges is illustrated in Figure 1 and consists in conditioning the sorbent, application of the sample and elution. When cartridges are used, the sample normally moves at flow rates of 5–10 mL min^{-1} to avoid the formation of preferential channels in the sorbent bed that could reduce the adsorption of the analytes towards the sorbent. After sample application, the sorbent is washed with water or solvent to remove impurities, then dried for 5–30 min to displace the excess of water or solvent. Depending on the application, especially if GC analysis is performed, complete drying of the sorbent (under vacuum or with nitrogen) is required before proceeding to the elution step. This drying step may enhance losses of more polar and volatile compounds. The trapped analytes are eluted with 5–20 mL of solvent, generally methanol, acetonitrile, dichloromethane, ethyl acetate, hexane, etc., or mixtures of those, which are applied in two or more steps. A common practice to enhance recoveries is to let the elution solvent soak the sorbent for several minutes before elution. After elution, the excess of elution solvent is evaporated either by rotary evaporation or under a gentle stream of nitrogen to a final extract volume of 0.1–1 mL, depending on the initial concentration of pesticides. A mild evaporation process is usually recommended and dryness should be avoided to prevent important analyte losses. From this extract, an aliquot is injected into the chromatograph.

Figure 1 Off-line SPE process using SPE cartridges. The procedure includes (1) conditioning of the precolumn, (2) sample loading or preconcentration step, (3) elimination of the interferences and (4) elution of the analytes. (Reprinted from 'Handbook of HPLC' eds. E. Katz, R. Eksteen, P. Schoenmakez, N. Miller, with permission of Marcel Dekker Inc.)

Application of SPE cartridges for OPPs extraction include the use of Sep-Pak C_8 and C_{18}.[38,39] XAD resins have been used for extraction and stabilization of pesticides from water.[40] However, this sorbent needs an extensive cleanup prior to the preconcentration step.[41]

The main advantages of using cartridges is that manipulation, solvent disposal and analysis time are reduced in comparison with conventional LLE techniques. Percolation of water samples can be done manually, but nowadays automated devices such as the ASPEC XL from Gilson (France) or the Zymark system (USA) permit the automation of the technique, making it useful for routine analysis. In environmental applications, it is interesting to obtain high enrichment factors so that one can achieve high sensitivity. This can be accomplished with off-line SPE, since there is a great choice of SPE sorbents, with different capacities, and therefore high sample volumes can be percolated. Prior to SPE, surface water samples have to be filtered through 0.45 μm filters to remove sample particles and to avoid clogging of the SPE cartridges. However, filtration may result in poor recoveries of the most apolar compounds, such as temephos, trifluralin and others, which, being preferentially adsorbed on particles, are removed from the aqueous sample together with the particles. In SPE, the extraction efficiency depends on the type of water matrix concerned. In general, drinking or groundwaters produce better recoveries and DLs, since the amounts of interferences are very low. In contrast, when preconcentrating surface or wastewaters, impurities are also preconcentrated, so that worse quality parameters are achieved.

An alternative to off-line SPE with cartridges is the use of Empore extraction disks and Speedisks (Baker, The Netherlands), where the sorbent particles are meshed in Teflon fibrils to form strong sheets or

membranes which can be used in standard filtration devices. Since the channeling phenomenon does not occur in the disk format, higher sample flow rates can be applied in comparison with cartridges. The main drawback is that automation is not straightforward. Recently, a new disk format has appeared on the market, the Speedisk, and it is provided with, in addition to the active sorbent, a mesh which acts as a filter and, therefore, filtration and extraction are performed in a single step. With these disks, the sample flow rate can be increased to 200 mL min^{-1}, which is interesting from the viewpoint of routine analysis of industrial and wastewater samples, which normally contain large amounts of particulate material. The overall conditioning and extraction time using Speedisks is 10 min. Moreover, racks of six positions are available, which means that six samples can be processed simultaneously in 10 min. Barceló et al.[42,43] have applied Empore extraction disks in OPPs analysis and more recently Speedisks have been used to extract several pesticides from surface waters.[44]

3.2.2 *On-line Solid-phase Extraction Methods*

A different approach for SPE is the use of on-line systems. In this case, the sorbent is packed in a stainless-steel or Teflon cylindrical precolumn, which can be used under pressure, and is connected on-line with LC or GC. Typical on-line methods for extraction of pesticides were described by Nielen et al.[45] and Brinkman.[46] The set-up is very simple and is illustrated in Figure 2. The water sample containing the pesticides is pumped, via an inexpensive pump, to the precolumn, which is placed at the loop position of a six-port valve. After preconcentration of the water sample, the valve is electrically switched from the preconcentration position to the elution position and the pesticides are desorbed by the mobile phase and are directed to the analytical column where separation will take place. The main advantage of on-line systems is that they can be fully automated, which makes them specially suitable for routine monitoring programs. The Prospekt (Spark Holland, The Netherlands) and OSP-2 (Merck, Germany) are the two systems commercially available for automated on-line preconcentration. The two systems have their own precolumn design, which covers a large variety of packing materials and includes the possibility of elution in normal and backflush modes.

Parameters that can be optimized for on-line SPE are the volume of water to be preconcentrated, the flow rate, normal or backward elution and type of sorbent used. However, in order to achieve optimal performance with on-line SPE, the sorbent of the precolumn should be as similar as possible to the analytical column packing

Figure 2 General diagram of the system used for on-line preconcentration and determination of OPPs in water samples. (Reprinted from 'Handbook of HPLC', eds. E. Katz, R. Eksteen, P. Schoenmakez, N. Miller, with permission of Marcel Dekker Inc.)

in terms of type of packing, particle size, etc., to avoid band broadening which can appear specially when normal flush elution is used. Owing to band broadening, quantification of on-line SPE samples with direct injection is not advisable and Pichon and Hennion[47] indicated a 5% error if quantification of on-line samples was compared with direct injection. Band broadening can be minimized by using a suitable gradient which causes peak compression on the top of the analytical column. The size of the precolumn is also of importance because the elution profile of the analytes should be as narrow as possible, especially at the beginning of the separation, where the high water content tends to cause peak distortion. Precolumns are generally 2 mm long and 2–3 mm i.d., and are packed with 10–60-μm sorbent material which efficiently traps the analytes while precolumn clogging is prevented. This design is adapted for classical analytical columns of 15–25 cm × 0.46 cm i.d.

Recently, a prototype has been developed by Hewlett-Packard where on-line SPE with LC/DAD has been coupled on-line with a filtration device and refrigerated reservoirs. Such a system is controlled by a unique software and it is totally automated, from sample collection and filtration to the final chromatographic analysis.[48] This is a useful approach for the routine monitoring of pesticides in situations where it is necessary to control the water quality over a long time (e.g. depuration plants).

An alternative to SPE coupled with LC is the coupling of SPE on-line with GC.[49] This system, known as SAMOS GC, includes the preconcentration unit Prospekt (Spark Holland), an HP 6890 gas chromatograph and an HP Chemstation. Interfacing SPE with GC is the most critical part of the system and it includes a retention gap and a retaining column prior to the analytical column. The different interfaces have been discussed by Brinkman et al.[46,50,51] SPE with GC has been coupled to flame ionization detection (FID), NPD and MS with an HP 5973 mass-selective detector. In general, the preconcentration of 1–10 mL of river water is sufficient to quantify pesticides at concentrations of 30–100 ng L^{-1}.[52]

On-line methods have the advantage that they can be easily coupled to both LC and GC, making these techniques suitable for the analysis of pesticides in water. In relation to these techniques, the use of small precolumns permits the miniaturization and total automation of the preconcentration technique. DLs at the nanograms per liter level and excellent reproducibility can be obtained by using the on-line approach because the entire sample is transferred to the analytical column and losses during sample manipulation are minimized. As a result, degradation studies can be followed without risk of degradation of pesticides during the extraction procedure. An additional advantage is that by using different types of sorbent it is possible to fractionate the extraction of compounds of different chemical classes.

Another methodology designed for a fast extraction and detection method has been developed by Brinkman's group.[54] The technique, known as single short column (SSC), consists in a unique column 3 cm long in which extraction of the analytes is done at the same time as they are separated. These columns are packed with C_{18} or polymeric sorbent and differ from that of a conventional analytical column because they have a higher particle and pore size. As a result, a slight separation of the analytes is performed and, upon elution, the analytes are detected. Similarly to conventional on-line systems, this unique column is coupled to the chromatographic system, and after pumping the water through the SSC desorption takes place on passing the mobile phase through the column. However, ideally an MS detector is necessary to achieve selectivity and unequivocal identification. Hogenboom et al.[55,56] detailed the application of the method for water monitoring and indicated that it can be used to identify and even to quantify the analytes. The main advantages of the system are its simplicity and that it consists of a cheap method, which is useful as a screening method for samples that, often, contain small amounts or no trace of pesticides.

Similarly to cartridges, disposable SPE precolumns can also be used for the storage of pesticides. Lacorte et al.[53] have used the precolumns of the Prospekt (Spark Holland) for stabilizing 19 OPPs extracted from water samples. Table 3 reports the percentage recoveries of selected OPPs after storing the loaded precolumns at room temperature for 1 month, at 4 °C for 3 months and at −20 °C for 8 months. It can be seen that −20 °C is the best option to avoid degradation. The main advantages reported are the easy transport of the sample and the simplicity and low cost of storing water samples.

Table 3 Average percentage recovery ($n = 3$) of OPPs stored at room temperature (RT) for 1 month, 4 °C for 3 months and −20 °C for 8 months

Compound	λ (nm)	RT (1 month)	4 °C (3 months)	−20 °C (8 months)
Mevinphos-*cis*	220	n.f.	35	22
Mevinphos-*trans*	220	n.f.	19	58
Dichlorvos	220	59	n.f.	55
Fensulfothion	254	123	74	89
Azinphos-methyl	220	115	100	111
Fenamiphos	254	n.f.	n.f.	101
Phosmet	220	39	61	34
Pyridafenthion	254	84	n.c.	100
Parathion-methyl	280	117	109	105
Malathion	220	116	n.c.	124
Fenitrothion	254	112	91	108
Azinphos-ethyl	254	112	91	108
Chlorfenvinphos	254	114	90	106
Fenthion	254	89	85	103
Parathion-ethyl	280	111	104	109
Coumaphos	280	117	103	113
Fonofos	254	n.f	n.f.	107
EPN	220	99	103	83
Chlorpyrifos	220	88	104	133

Analyses were performed using on-line LSE with LC/DAD. Quantification wavelength is indicated (λ). Volume of water preconcentrated = 26 mL, spiked at 10 ng mL^{-1}. n.f. = not found; n.c. = not calculated/impossible to quantify.

3.3 Types of Sorbent Materials

A wide range of sorbent materials are available today in different configurations. Even though bonded silicas such as C_{18} or C_8 are still the most commonly used materials for environmental analysis, polymeric sorbents have become a good alternative for the effective preconcentration of moderately to polar organic compounds.[57,58] Polymeric sorbents are available from most manufacturers under various trade names such Envi-chrom, PLRP-S, Lichrolut EN, Isolute ENV, Oasis, etc., the main differences among them being the pore and particle size distribution. Modifications such as acetylation[59] or sulfonation[60] have a mixed retention mechanism consisting in hydrophobic and ionic interactions which facilitate the trapping of the most polar pesticides and increase recovery values. DiCorcia et al.[61,62] described the use of GCB for analyzing phenols, but it has not been widely applied

for the analysis of OPPs owing to excessive retention of the most apolar compounds. The poor mechanical stability of GCB has prevented its routine application in the on-line approach. This problem was solved by the development of porous graphite carbon (PGC), where the graphite is immobilized on a silica structure and the phase is pressure-resistant and shows better stability.[63] In general, PGC precolumns should be coupled with a PGC analytical column to prevent band broadening.

Anion exchangers are also applied for the analysis of very polar analytes which are not trapped using polymeric phases. Combination of various sorbent materials such C_{18}, GCB or PLRP-S with an anion exchanger are useful for extracting analytes of different polarities and can be used with both on-line and off-line procedures. Connection of two precolumns can also be used for sample cleanup, since one adsorbent is used to trap the analytes of interest while the other retains the matrix impurities.

Some limitations of conventional SPE materials are related to their non-selectivity because they are based on polar and hydrophobic interactions capable of retaining humic and fulvic acids and other water matrix compounds and the incapacity of retaining very polar compounds. These problems have led to the development of new sorbent materials, which are based on specific interactions between the target analyte and the sorbent, and have the property of specifically retaining the analytes for which they have been designed. Really promising is the development of different types of immunoaffinity sorbent (IS) or immunosorbent[20] and molecular imprinted polymer (MIP)[64] for SPE. In the case of IS, by taking advantage of cross reactivity, trapping capacity and selectivity, single analytes or families of compounds of equal chemical nature can be extracted, thus avoiding matrix interferences. This approach has recently been applied for pesticide analysis and Pichon et al.[20,65] and Ferrer et al.[66] reported the breakthrough volumes of several herbicides obtained with immunosorbents. So far, immunosorbents have not been developed for OPPs.

The other newly developed alternative to conventional SPE is the use of MIPs, which act in a similar way to antibodies since the interaction between the analyte and the polymer is also highly selective. In contrast to IS, MIPs are synthesized chemically. They consist of synthetic polymers obtained by polymerizing a monomer with a cross-linking agent around a template (analyte). The sorbent is packed in cartridge format. The preconcentration takes place owing to the cavities on the polymer left after washing the template. These cavities will selectively bind the target analyte and structurally related compounds. As in the case of IS, it consists in a selective preconcentration where no further cleanup step is required. MIPs have started to be used for analyte SPE mainly in the pharmaceutical area. The principal application of MIPs is in areas where a specific recognition of particular molecules is needed and antibodies are not available. In these cases, conventional sorbents are not useful since an efficient cleanup is necessary to avoid matrix interferences.[67] In environmental applications, MIPs have been developed for atrazine, which is a well-known herbicide, as an ideal compound. In this area of application, only model conditions have been used, such as preconcentration of distilled water, and the extraction procedure is still under development, since the extraction efficiency depends on parameters such as solvent composition and pH.[64] The development of MIPs for OPPs is a promising approach which will permit selective extraction from both water and food samples.

The main advantages of IS and MIPs over conventional SPE sorbents is that since there is a selective molecular recognition to capture the target analyte, they permit a selective extraction of the sample without the need for further cleanup. Therefore, a high degree of sample preconcentration and purification can be achieved with IS and MIPs. Straight benefits will be for samples in which the impurities co-extracted with a conventional reversed-phase sorbent interfere in the chromatographic analysis, e.g. with diode-array detection (DAD), or suppress the ionization process in the case of MS detection.

3.4 Parameters Involved in Solid-phase Extraction

Owing to the large variety of packing materials, sizes and formats, the extraction efficiency for both off- and on-line modes will vary depending on the nature of the analytes and on the sample matrix. The most critical parameter in SPE efficiency is the breakthrough volume, or the maximum volume of water that can be preconcentrated upon an adsorbent without producing losses of a particular analyte. The breakthrough volume depends on the polarity of each analyte, on its affinity for a particular type of sorbent and also on the amount of sorbent, and therefore will vary from pesticide to pesticide. In on-line methods, breakthrough of the more polar pesticides is originated by the restricted size of the precolumns. This does not happen with off-line procedures since the amount of sorbent is not a limitation and, therefore, higher breakthrough volumes are obtained. Different methods for calculating the breakthrough volumes are described in a review by Barceló and Hennion[68] and involve the study of breakthrough curves or empirical estimation from elution chromatography.[69,70]

In addition to the physicochemical properties of each pesticide, the breakthrough volume will also depend on the type of water. The analysis of environmental waters gives, in general, lower breakthrough values than the

analysis of drinking water. This is due to the presence of humic and fulvic acids, which can bind organic contaminants and decrease the recoveries since only the dissolved fraction will be enriched.[71] As mentioned by Senseman et al.,[72] the type of water can notably affect analytical performance. An important parameter that affects the extraction efficiency is the pH, and the sample pH should be optimized to maximize the analyte recovery and DLs. Acidification of the sample is a common practice in environmental analysis because it can prevent the deprotonation of the most acidic compounds and inhibit microbiological degradation. However, acidification can raise the hydrophobic character of humic material and lead to higher absorption of the humic material into the sorbent. Those analytes which lack a strong affinity for the sorbent will have lower breakthrough volumes since there is strong competition between the analytes and the humic substances. The humic acids appear in the chromatogram as a large unidentified complex matrix (UCM) interfering peak.[57] Humic material can be partially removed from the sorbent by passing a small amount of water through the sorbent bed after percolating the sample. However, it should be taken into consideration that the washing step can lead to a decrease in recovery because when removing humic material analytes will also be removed. Therefore, the water volume should be carefully optimized, especially when working with low breakthrough volume analytes.

4 COLLECTION AND PREPARATION OF FOOD SAMPLES

Owing to food QC and regulations on QA, OPPs have to be monitored in all agricultural food samples before they are introduced to the market.[73] The major input of pesticides on agricultural products is attributed to direct pesticide application for crop protection and contamination through polluted groundwater irrigation. Food poisoning by OPPs in different food matrices has been reported by Lee et al.[74] and Miyamara et al.[75] The literature regarding the analysis of OPPs in milk and cheese,[76,77] oils and butterfat,[78,79] vegetables,[80,81] eggs[82] and grain,[83] among a long list, refers to different extraction procedures. A comparison of several detection techniques was made by Lee and Wylie.[84] The analysis of food samples differs considerably from that of water samples, and will be discussed below.

4.1 Collection of Food Samples

Meaningful residue data in food samples can only be obtained if careful sampling and collection have been performed. Therefore, the sampling plan should be well studied in relation to the type of pesticide considered and the matrix to be studied. The sample should be representative of a whole population, and should be gathered according to the level of pesticides that have to be determined. Special care should be taken during sample collection to avoid nonrepresentative or spoilt samples. The correct procedure is to collect random grab samples of a whole population, mix the grab samples and reduce the sample size to a final laboratory-size proportion. However, the nature of the matrix will influence the sampling plan. The *Manual of Pesticide Residue Analysis*[85] reviews the sampling procedures for and analysis of OPPs in different types of food. It is established that for homogeneous products, 0.5–1 kg is sufficient for analysis. For products consisting of small units, sampling should be performed depending on the weight of each unit, e.g. 50 units (1 kg) for items of less than 25 g, 30 units (1–3 kg) for items of 25–100 g, 15 units (2–5 kg) for items of 100–250 g and at least 10 units for items larger than 250 g. After collection, food samples should be immediately transported to the laboratory in suitable conditions (normally refrigerated) in order to avoid degradation of the pesticides or spoilage of the sample matrix.

4.2 Analytical Preparation of Food Samples

Upon receipt, samples should be processed immediately, or otherwise stored at 4 °C or preferably at −20 °C. Before analysis, it is common practise to check the food sample and note the appearance, aroma, possible deposits, etc. All the physical characteristics should be described, which will aid in interpretation of the final result. Moreover, at this stage, impurities such as stones, insects or rotten parts should be removed. The sample should never be washed before processing. The sample should subsequently be weighed and the number of units should be recorded. In some cases, non-edible parts, e.g. stems, peel, leaves and roots, should be removed and the concentration of residues is then established for the weight of the edible portion. In other cases, it is important to analyze the residue levels of OPPs in the outer sample surface. Of course, the proportion of the sample analyzed will depend on the aim of each study.

At this stage, the gross laboratory sample should first be composited in such a way that representative analytical size samples are obtained from it. This step will depend on the type of sample: whenever possible, material should be homogenized, ground and mixed; products consisting of small units should be quartered and two opposite quarters should be homogenized. For large samples units (cheese, melons, etc.) which cannot be homogenized entirely, aliquots should be gathered and finally homogenized. In any case, from the gross laboratory sample it should be possible to obtain several analytical-size samples, from

which one or two will be analyzed and the rest will be kept as a reserve. These samples should be kept at −20 °C and wrapped in aluminum foil or kept in glassware, to prevent further decomposition or contamination.

Once the sample has been homogenized and mixed, the pesticides should be extracted. Food samples are more complex to analyze than water samples since the former are far more diverse and differ in the matrix composition (presence of fats, sugars, etc.). The *Manual of Pesticide Residue Analysis*[85] describes extensively the different methods used to extract OPPs from different types of food matrices. In this section, only the most common extraction procedures will be mentioned. Since for food samples extraction is influenced by the matrix, the application of one extraction method or another will be basically dependent on the type of pesticide to be analyzed (polarity, K_{oc}, volatility, etc.) and on the type of matrix. In contrast to water samples, in most food samples it is often necessary to perform a cleanup step to remove impurities which would interfere or even suppress the analytical determination. For this reason, it is important to use a selective extraction procedure which will maximize sample cleanup and will permit the use of conventional chromatographic techniques for their analysis.

Freeze-drying is a common method for conditioning biota samples for the extraction of pesticides.[86] Freeze-drying of biological material is used before extracting the pesticides since it destroys cell membranes and thereafter the contact between the cell tissue and the extraction solvent is increased. Soxhlet extraction is the most usual method to extract pesticides from food samples, despite the sample manipulation and tedious work involved. The most common solvents used for this purpose are ethyl acetate,[32] acetone and methanol,[87] acetonitrile[88] and hexane.[89]

Nowadays, microwave energy is sometimes used to extract various types of organic compounds from sediment and food samples. However, a recent trial to extract 64 OPPs from onions using a microwave oven indicated that extraction and recovery are affected by microwave heating.

Many extraction methods have been developed to extract pesticides from food samples and the application of one or another depends on the food sample matrix. For instance, strong acids or alkalis are used to facilitate the extraction of pesticides from foods with a high lipid content. However, many OPPs are decomposed in such media. As a result, the sample is extracted at neutral pH and the fatty matrix is subsequently removed by a suitable and nondestructive cleanup step, usually column chromatography with silica gel, alumina or Florisil.[90,91] The last method is that adopted by the USEPA.[92]

Gel permeation chromatography (GPC) is another cleanup alternative, and can be used with low-pressure chromatographic columns in such a way that it permits the discrimination of compounds depending on their molecular size. Large biogenic compounds, such as lipids, are excluded from the pores of the polymeric material and are eluted before smaller analytes, which are retained in the column pores. The separation mechanism is a combination of size exclusion, adsorption and partition. The prevalence of one mechanism over another depends on the mobile phase and the pore size of the polymeric material chosen. Common elution solvents used in GPC are ethyl acetate–cyclohexane,[32] acetone–cyclohexane, acetone–light petroleum[93] and cyclohexane–dichloromethane.[94] Thirty-nine pesticides (including their major metabolites) were determined in fatty processed food using dichloromethane extraction and GPC with a Biobeads SX3 column and dichloromethane–cyclohexane as eluent, giving recoveries between 51 and 185%.[95] The same column has been used to clean up carrot extracts, indicating that the high pigment content of samples produced band broadening on the column.[96] A different approach consisting of accelerated solvent extraction and cleanup with GPC has been used to analyze OPPs, among others, in foods, indicating recoveries from 80 to 90% and precision below 10%.[97] GPC has been also coupled on-line with GC and has been applied to extract OPPs in olive oil.[98] Other authors have indicated an efficient extraction of olive oil with acetonitrile, with no need for sample cleanup prior to GC, and reported recoveries ranging from 74 to 118%, indicating that the column efficiency is not affected by co-extracted oil impurities.[99]

A less common approach for the cleanup of food samples is the use of normal-phase LC, with silica columns and dichloromethane–hexane or dichloromethane–pentane as eluent.[100] With this system, pesticides are the first compounds to elute, and the lipidic components elute at the end of the chromatogram.

SPE with extraction disks has also been used to extract OPPs in high-moisture foods (<2% fat) with no need for further cleanup, and better recoveries than using conventional LLE procedures were reported.[101] SPE has been used as a cleanup technique to extract OPPs from eggs[82] and from cereal flours[102] by using minicolumns prepacked with Florisil. A promising analytical technique to extract OPPs selectively from food samples is the use of IS or MIPs, but application in such matrices is still under development.

Other techniques to extract OPPs selectively without further cleanup consist of matrix solid-phase dispersion, which has been applied to extract OPPs from milk[103] and oranges,[104] while supercritical fluid extraction (SFE) permits better recoveries of several OPPs in comparison with Florisil cleanup.[105]

5 GAS CHROMATOGRAPHIC DETERMINATION

5.1 Gas Chromatographic Detectors

GC plays an important role in trace analysis. It is a well-known and widely established analytical technique and it is the official technique adopted by the USEPA (EPA Method 8140).[106] GC coupled to an NPD, FID or electron-capture detector (ECD), atomic emission detector (AED) or pulsed-FPD is still the most common technique for OPP analysis in different environmental samples. The main reasons are the low DLs that can be achieved and high selectivity which permits multicomponent analysis and minimizes the effect of the sample matrix. In general, GC detectors provide a linear range over various orders of magnitude and DLs at the low nanograms per liter level in water and nanograms per gram level in food samples. However, when using these detectors, the USEPA indicate the need to confirm the results by using two different GC columns of different polarity, usually a DB-5 and a DB-1701.[107] The use of different columns solves the risk of co-elution and avoids false-positive determinations in environmental water analysis. Lacorte and Barceló[21] carried out a systematic study with the aim of studying the retention times of 26 priority OPPs and various TPs in three different capillary GC columns. Another way to confirm the results is the use of GC with MS as the detection technique[14] for both qualitative (it provides mass spectral information) and quantitative purposes. GC/MS has been performed either with the EI technique, positive chemical ionization (PCI), negative chemical ionization (NCI) and tandem mass spectrometry (MS/MS) and has been widely applied for pesticide analysis.[86,108,109] Information that can be obtained with GC/MS is summarized below.

5.2 Gas Chromatography/Mass Spectrometry with Electron Ionization

One of the main advantages of GC/MS with EI is the existence of libraries which contain more than 120 000 spectra. EI gives very good reproducibility of the spectral data, even when using different mass spectrometers, so that identification and confirmation of the presence of OPPs in an environmental sample are performed by spectral matching. At the same time, GC/MS gives good sensitivity and can also be used for quantification purposes. EI is normally coupled with quadrupole mass analyzers, but magnetic sectors and ion traps can also be used. Different analyzers can lead to variations in the relative abundances in the EI mass spectrum. Various references with GC/MS data using EI for the analysis of OPPs have been published.[110–114] EI provides abundant fragmentation of the analytes but molecular weight information is scarce, since the molecular ion species, $M^{\bullet+}$ is not always observed. For this reason, the USEPA recommends the identification for one pesticide of at least three different ions. Upon fragmentation, OPPs produce diagnostic or characteristic ions which correspond to the functional group structure of each family of pesticides and permit their identification. Other fragment ions formed correspond to specific ions, and are typical of each compound. An extensive study reported by Wilkins et al.[115] was based on the identification of various OPP compounds by five typical rearrangements, with diagnostic ions corresponding to m/z values of 93, 97, 109, 121 and 125. A more recent study,[21] also concerning OPPs, gave information on diagnostic fragment ions obtained by GC/MS with EI as well as compound-specific ions, as indicated in Table 4. Various possibilities of tentative ion identification for the same fragment ion, e.g. m/z 97, 109, 127 and 137, are given. This qualitative information is valuable since it can be used for identifying OPPs and their TPs from complex environmental matrices. It was concluded that (i) diagnostic fragment ions reported in Table 4 usually correspond to a class of OPP compounds. In this sense, m/z at 109 and 125 are base peaks for the dimethylphosphates and dimethylphosphorothioates, respectively. (ii) In some cases, diagnostic fragment ions depend on the type of molecule and it is possible that two

Table 4 Typical fragment ions of OPPs in GC/MS with EI

m/z	Ion	Other possibilities
47	CH_3S^+

Reprinted from S. Lacorte, C. Molina, D. Barceló, 'Screening of OPP in Environmental Matrices by Various Gas-Chromatographic Techniques', *Anal. Chim. Acta*, **281**, 2451–2460, [21] Copyright (1995), with permission from Elsevier Science.

compounds will have an ion at the same m/z value but have different chemical compositions (indicating different families). This is the case of m/z 109, corresponding either to $(CH_3O)_2PO^+$ (methylphosphates), $(C_2H_5O)OHPO^+$ (ethylphosphates) or $(C_2H_5O)PSH^+$ (ethylphosphorothioates). The rearrangement ion at m/z 97 usually corresponds to $(OH)_2PS^+$ (phosphorothioate), but in the case of phosphorodithioates it corresponds to $(SH)_2P^+$. It is therefore useful to have the chemical structures of the different compounds since some of the fragment ions can then be predicted. (iii) The abundance of molecular ion species M^+ increases with its ability to sustain a positive charge and is related to the ionization energy, which is lower for S than O. Examples of this case include parathion-ethyl and fenitrothion, which show higher relative abundances of M^+ as compared with the oxo derivatives. (iv) The chlorinated compounds exhibit as main peaks the corresponding fragment ions with chlorine losses. (v) Specific fragments which are typical of some compounds are also observed, e.g. McLafferty rearrangement involving proton extraction by an oxygen of the nitro group indicating the presence of CH_3 adjacent to an NO_2 group, as for fenitrothion and fenitrooxon.

The sensitivity of GC/MS can be increased by one order of magnitude by using selected ion monitoring (SIM), where only a few ions are recorded. By selecting appropriate diagnostic and specific fragment ions of OPPs, quantitation of environmental samples can be performed at the parts per billion level and the technique can be routinely applied in monitoring studies. In general, the use of higher m/z values is preferred since better selectivity is obtained and matrix interferences are minimized.

5.3 Gas Chromatography/Mass Spectrometry with Chemical Ionization

GC/MS with either PCI or NCI consists in a soft ionization technique which gives molecular weight information that EI spectra rarely give. In CI a reagent gas, normally methane, isobutane or ammonia, is used for the ionization process. CI mass spectra are not as reproducible as with EI, since many parameters are involved in the ionization process. The reagent gas used, the reagent gas pressure applied and the source temperature affect the fragmentation pattern and the sensitivity. It is for this reason, and because mass spectra are very much dependent on the instrument type, that there are no libraries of spectra available for CI mass spectra. Of the two modes of ionization, NCI is more selective and sensitive than PCI and EI and it is the preferred option for the determination of OPPs with electron-withdrawing groups (nitro- or chloroaromatic groups).[108,109,116,117] The molecules of the so-called parathion-like structure offered high sensitivity under the negative ion conditions owing to the presence of an aromatic moiety which is accompanied by a nitro group, thus forming a kind of pseudoacid by electron attachment which stabilizes the negative charge.

When this aromatic moiety contains other electron-withdrawing groups, e.g. chlorine atoms, the stabilization of the negative charge and sensitivity are also enhanced. The sensitivity can be increased by two orders of magnitude compared with GC/MS with EI.[108,116] Table 5 lists the diagnostic ions of the different OPPs, which are characteristic of the different chemical groups. The following general remarks can be made. (i) The diagnostic ions formed under NCI are, in many cases, the base peaks of the analytes and, in some cases, the only spectral information obtained. This is a typical characteristic on MS with NCI of OPPs, so their unequivocal identification should always be performed in combination with the retention time. (ii) The formation of M^{*-} has a 100% relative abundance for the OPPs of the so-called parathion group, and compounds having an aromatic moiety (with the exception of chlorinated OPPs). This is due to the fact that M^{*-} is fairly stable under NCI conditions when an aromatic moiety exists in the molecule, and is even more important when a nitro group is present. (iii) The chlorinated OPPs with an aromatic moiety have intense or base peaks corresponding to losses of Cl, such as CH_3Cl or HCl, owing to the facility of such processes under NCI conditions. (iv) The formation of thiofenolate versus fenolate ions for compounds such as parathion, fenitrothion, coumaphos and fenchlorfos is due to their stronger acidity in the gas phase and there is a transfer from the aromatic moiety from the oxygen to the sulfur atom.

Complementing GC/MS with EI and NCI is useful in environmental analysis because some compounds will give a better response under one type of ionization mode whereas others, with different structural characteristics, give a better signal under the another. Moreover, the use of two GC/MS techniques is a means of confirming the presence of pesticides in environmental matrices

Table 5 Diagnostic ions of OPPs with GC/MS and NCI

m/z	Ion	Group
125	$(CH_3O)_2PO_2$	Dimethylphosphates
141	$(CH_3O)_2POS$	Dimethylphosphorothioates
153	$(C_2H_5O)_2PO_2$	Dimethylphosphorothionates
157	$(CH_3O)_2PS_2$	Dimethylphosphorodithioates
169	$(C_2H_5O)_2POS$	Diethylphosphorothioates

and, more importantly, it permits the unequivocal identification of TPs that might be formed in environmental samples. Such an approach was used to follow the degradation kinetics of fenitrothion after being applied in the environment for eradicating the crab *Procamburus clarkii*. Fenitrooxon, the *s*-methyl isomer of fenitrothion and 3-methyl-4-nitrophenol were detected as the main TPs of fenitrothion by GC/MS with both EI and NCI, and trace levels were found in water 4 days after application.[6] Such techniques permitted the concentration of fenitrothion to be monitored for 7 days, which was useful for determining the half-life. Under the field conditions and at water temperatures of 10–13 °C, the half-life of fenitrothion was estimated to be 13 h. The evolution of the levels of fenitrothion under environmental conditions are shown in Figure 3. Figure 4 shows the degradation pathway of fenitrothion under these conditions. It can be concluded, therefore, that GC is a powerful technique in environmental water analysis, owing to the separation efficiency, the wide availability of detectors, including MS, and the possibility of performing degradation studies. However, one of the limitations of GC/MS is that polar, non-volatile or thermolabile pesticides cannot be directly analyzed without a derivatization step.[118] Derivatization increases sample manipulation and time of analysis and introduces new sources of errors. For such reasons, there is a general tendency to switch to LC, which can overcome the aforementioned limitations.

Figure 3 Evolution of the levels of the concentration of fenitrothion [plotted as logarithm of concentration versus time, giving both measured values and calculated values, according to the first-order rate Equation (1)] and its TPs after application of fenitrothion in the field at a concentration of 200 µg L^{-1}. 6 HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

HPLC has become popular for the analysis of compounds that are not amenable to GC. The increasing development of HPLC techniques has led to the sensitivity needed to meet EU legislation for the analysis of polar pesticides in surface and food samples. In HPLC the mobile phase flows through the stationary phase and separation of the analytes takes place owing to the interactions between the solute, the mobile phase and the sorbent. In environmental applications, reversed-phase chromatography is the most common separation mechanism used in HPLC, although other approaches such as adsorption, ion-exchange and size-exclusion chromatography (SEC) can also be used. Stationary phases used in reversed-phase chromatography are alkyl- or phenyl-bonded silicas, polymeric materials or carbon-based sorbents. By using methanol, acetonitrile, water and tetrahydrofuran (THF) or combinations of them, it is possible to separate pesticides over a wide range of polarities, including their TPs. Since HPLC techniques can be applied to non-volatile, thermolabile and polar compounds, it is becoming the favored technique for OPP analysis. An additional advantage over GC is that on-line SPE and postcolumn systems are easily compatible with

LC. This feature combines the extraction step and chromatographic analysis in a single, totally automated step, which is an interesting property from the viewpoint of routine analysis and reduction of sample manipulation.

HPLC can be coupled with various types of detectors, such as UV and fluorescence detectors, DAD and mass spectrometers, which make the techniques robust and adapted to each experimental requirement. Coupling LC with MS is not as obvious as with GC/MS, since the mobile phase has to be eliminated before entering the mass spectrometer and at the same time ions have to be generated. A book[119] has been published that provides an overview of the different LC/MS applications for environmental analysis. Several interfaces have been designed to overcome the problem: trace enrichment (PB and moving belt) and nebulization (TSP and API interfaces). Trace enrichment interfaces have the advantage that they can provide EI mass spectra but their application in the environmental field has been reduced owing to their low sensitivity and poor reproducibility. For this reason, these interfaces will not be treated in this article and all the discussion will be focused towards DAD and nebulization devices.

6.1 Liquid Chromatography with Diode-array Detection

Recent developments in DAD permit the achievement of DLs in the nanograms range and a UV visible spectra can be recorded so that the analytes can be identified by spectral comparison against a standard previously injected. Pesticides susceptible to absorbing UV radiation are those which present a suitable chromophore and in general they present a typical UV spectrum with a maximum between 230 and 280 nm. Modern instruments can monitor between 190 and 800 nm, at a rate up to one spectrum per second, which permits very good spectral resolution. Moreover, most software includes the peak purity analysis of each detected compound which indicate potential co-elution problems with another pesticide or with matrix interferents. These two characteristics are very useful since it is possible to distinguish compounds of the same family that can have very similar UV spectra. At the same time, pesticide TPs have spectral similarities with their parent compounds, and there is only a slight shift in the absorbance spectra. By setting the acquisition parameters to obtain good resolution, it is possible to identify chemically related compounds. This characteristic makes HPLC with DAD the most common detection method for pesticide analysis in water and food samples. Peak identification with LC/DAD is usually carried out by means of the retention time in comparison with a standard and by spectral matching through a library search, an option which is nowadays included in most software. Selectivity can be enhanced by choosing an appropriate UV wavelength which permits the identification and quantification of pesticides with very close retention times and even a reduction in the contribution of matrix interferences. Therefore, it is recommended to perform quantitative analysis at the wavelength which provides better calibration adjustment. Peak purity analysis is also important to achieve good accuracy.

A review describes the applications of LC/DAD and other detection techniques for the determination of polar pesticides and related compounds in aquatic samples.[120] Other papers report the use of LC/DAD to monitor OPPs in surface waters, either using on-line SPE[121–123] or off-line methods.[124] The main drawbacks related to DAD are due to the poor selectivity when analyzing complex environmental samples which contain large amounts of humic and fulvic material or other interferents. At this point, sample pretreatment should be optimized, especially the cleanup step to remove interferences which appear especially when working at low wavelengths. At the same time, DLs are increased by this matrix effect.

6.2 Liquid Chromatography and Mass Spectrometry with Thermospray Interface

Liquid chromatography coupled to mass spectrometry with a thermospray interface (LC/TSPMS) has been widely used to determine organic contaminants in water matrices[125,126] and has been adopted by the USEPA (Method 8321)[127] for the analysis of OPPs in different types of water matrices. The LC/TSPMS interface consists of sample nebulization and ionization through a heated capillary. It is a soft ionization technique which produces molecular peak spectra and scarce fragment ions. The spectral pattern depends on the additives added to the mobile phase, which are mainly ammonium acetate or formate. Ionization is due to gas-phase protonation reactions between the analyte and the ammonium.[26,128] The main disadvantage of LC/TSPMS is that it gives poor structural information. This can be solved by using filament-on or discharge assisted ionization which generates solvent mediated ionization similar to direct TSP ionization (without additives) and sensitivity is enhanced.[129] The use of liquid chromatography coupled to tandem mass spectrometry with a thermospray interface (LC/TSPMS/MS) is the best choice to enhance fragmentation of quasimolecular ions[130] and it offers collision-induced dissociation (CID) spectra and is used for both identification and quantification purposes. However, this is an expensive instrument which cannot be afforded by most laboratories.

Ion formation in TSP in the positive ionization (PI) mode generates $[M + H]^+$ and the ammonium adduct $[M + NH_4]^+$ as base peaks for pesticides, depending on the proton affinity of each compound. In the negative ionization (NI) mode, $[M - H]^-$ or acetate or formate adducts are formed. The NI mode is more sensitive and

selective for the analysis of electronegative compounds, such as chlorinated OPPs.

The characterization of several pesticides by LC/TSPMS in PI and NI modes using filament-on ionization was detailed by Lacorte and Barceló,[126] who remarked that little or no fragmentation is observed for many of the pesticides. This represents a drawback since the identification of unknowns in environmental samples (e.g. TPs of OPPs) becomes difficult. The requirement set by the USNPS, in which at least three different ions are needed to confirm unequivocally the presence of a pesticide in a real water sample, generally is not accomplished by using LC/TSPMS. Rather than compound identification, LC/TSPMS is more useful for target compound analysis. Under full-scan conditions, instrument detection limits (IDLs) are around 1 ng for pesticides.[131]

Sensitivity can be enhanced by coupling SPE on-line with LC/TSPMS. This approach has been used to quantify and identify OPPs and their TPs in environmental matrices.[126,132,133] On-line SPE coupled with LC/TSPMS and on-line SPE coupled with LC/DAD have been used to follow the degradation of several OPPs in seminatural conditions (river water spiked at a low concentration level and exposed outdoors for 4 weeks).[10] The half-life measured as $t_{1/2} = \ln 2/k$ indicated that pesticides persisted in such conditions for 6–12 days. However, when degradation occurred, confirmatory analysis of pesticide TPs was carried out by means of MS detection with a TSP interface. The oxo derivatives of chlorpyrifos-methyl, diazinon, isofenphos, pyridafenthion and temephos were detected 4 weeks after sunlight exposure. In general, the oxygen analogues could be identified since they followed the same adduct formation as the parent pesticide and eluted before the parent compound. Figure 5(a–c) shows the LC/DAD and LC/TSPMS chromatograms of a water sample spiked with chlorpyrifos-methyl and analyzed after 4 weeks. Whereas LC/DAD detected chlorpyrifos and a TP not unequivocally identified, LC/TSPMS in the PI and NI modes confirmed the presence of chlorpyrifos (*m*/*z* 323), its oxo derivative (*m*/*z* 324) and 3,5,6-trichloro-2-pyridinol (*m*/*z* 198). Chlorpyrifos and the two TPs identified exhibited losses of chlorine atoms and proton abstraction, similarly to the parent compound. The toxicity of 3,5,6-trichloro-2-pyridinol is greater than that of chlorpyrifos, with EC_{50} values of 18.6 and 46.3 $\mu g\,mL^{-1}$, respectively, calculated with the Microtox system.[134] Also, it has been reported that this compound is toxic to soil microorganisms and results in less mineralization and therefore enhanced persistence of chlorpyrifos in soil. This example indicates the importance of analyzing TPs and the need to include them in the analytical methods.

Although LC/TSPMS affords some structural information, often more fragment ions are needed for confirmatory purposes. LC/TSPMS/MS techniques or API interfaces can solve the problem, since they can produce spectra by CID. An additional drawback of LC/TSPMS is the high intraday signal variations, which lead to poor reproducibility. For these reasons, many laboratories tend to switch to the new API interfaces which nowadays is the preferred option for the analysis of pesticides in environmental samples since it is a more robust technique. API includes several interfaces, i.e. ESP, the high-flow pneumatically assisted ESP, commonly named ISP, the heated pneumatic nebulizer (HPN) and APCI. The main

Figure 5 Reconstructed ion chromatograms obtained with on-line LSE with LC/TSPMS with (a) PI and (b) NI mode of ionization of an Ebre river water sample spiked with chlorpyrifos-methyl at 50 $\mu g\,L^{-1}$, and analyzing the water sample 4 weeks after spiking. Peak identification: (1) 3,5,6-trichloro-2-pyridinol; (2) chlorpyrifos-methyl oxone; (3) chlorpyrifos-methyl. (c) Same water sample analyzed by on-line SPE with LC/DAD at 280 nm. (Reprinted with permission from Elsevier Science.)

advantage of these interfaces is their higher sensitivity for OPP analysis compared with TSP or PB.[135–137]

6.3 Liquid Chromatography and Mass Spectrometry with Electrospray/Ionspray Interfaces

Electrospray/ionspray (ESP/ISP) consists in applying a voltage to a capillary that ionizes the solvent extract with the pesticides, which emerge from the capillary as a spray. This spray contains microdroplets which are positively or negatively charged, depending on the difference of potential between the capillary and the counterelectrode. In the desolvation chamber, the droplets undergo ion evaporation and ions escape to the gas phase. Such ions are then focused towards the quadrupole of the mass spectrometer. In electrospray/ionspray mass spectrometry (ESP/ISPMS), 90% of the ions are formed in solution and at atmospheric pressure. The main advantage of ESP/ISP techniques is that no heat is applied to ionize the samples, eliminating thermally assisted degradation, as happens when using a GC or TSP interface. This allows the LC/MS analysis of thermolabile analytes such as trichlorfon,[138] which is a compound that has been shown to suffer thermal degradation under LC/TSPMS caused by the probe tip and gas-phase temperatures higher than 200 °C. The major differences between these two interfaces is that in ESP only 10–80 μL min^{-1} can be directed to the source, whereas in ISP flow rates from 300 to 1000 μL min^{-1} can be applied. A few applications using ESP have been undertaken for OPPs.[29,139] In ESP it is necessary to use syringe LC pumps, or otherwise when using conventional LC pumps a splitting device should be used.[140] In ISP, higher flow rates (up to 1500 μL min^{-1} in the new-generation interfaces) can be handled; a gas flow, normally nitrogen, is applied in the interface and acts as a nebulizer. After nebulization of the liquid, a heated drying gas is applied countercurrent and droplet evaporation is facilitated by breaking the analyte–solvent clusters at the desolvation chamber. The drying gas also prevents clogging of the sample orifice. With ISP, ions emerge from the capillary owing to the simultaneous action of the nitrogen and the capillary voltage set at 2–4 kV.

Ion formation in ESP/ISP is due to the evaporation of ions from charged droplets, which results in ions with very little internal energy and, therefore, molecular or quasimolecular ions are formed with little or no fragmentation. To enhance fragmentation, an extraction potential of 10–200 V, depending on the particular design of the interface, is applied at the extraction cone. This potential focuses the spray towards the sample orifice and into the high vacuum of the mass spectrometer. An increase in this potential accelerates the ions and the collisions between them induce fragmentation via CID. In some cases, an increase in the cone voltage can lead to a decrease in sensitivity. Therefore, careful optimization of the cone voltage is required and generally a compromise between structural information and sensitivity has to be achieved.

In ESP/ISPMS, methanol or acetonitrile and water are generally used as mobile phase. When working in PI and at low extraction voltage (e.g. 20 V), the formation of $[M + H]^+$ and $[M + Na]^+$ is favored and these are generally the base peaks. The generation of $[M + Na]^+$ is more common when methanol is used in the mobile phase since the Na^+ ions are due to impurities in the methanol solution. On increasing the extraction voltage, fragmentation occurs at the expense of $[M + H]^+$ ion and results in diagnostic or compound-specific fragment ions.

ISP under PI permitted DLs at the picogram level to be achieved for selected pesticides. Sensitivity problems for the parathion group (parathion-methyl, parathion-ethyl, fenitrothion and fenitrooxon) were noticed when using ISP or conventional ESP.[29] The ionization of these compounds under ESP conditions offers problems and generally it is difficult to achieve low nanograms per liter DLs in water samples. In general, the repeatability and the long-term reproducibility ($n = 9$) for OPPs vary from 12–17 to 22–30%, respectively, on injecting 1 ng of each compound, which is better than that obtained by using LC/TSPMS.

A remarkable fact is that typical diagnostic ions of OPPs formed in liquid chromatography coupled to electrospray/ionspray mass spectrometry (LC/ESP/ISPMS) are similar to those in EI. The formation of diagnostic ions at m/z 109, 110, 125 and 141, to mention some, permits the identification of each family of pesticides. This is an important feature, which is not accomplished by TSP, and therefore these techniques can be used for the identification of pesticides and their TPs in environmental samples. Moreover, more structural information is obtained at 40 V or higher voltages (compared with 20 V) and permits the easy identification of nontarget pesticides in environmental samples.

The use of ISP in NI has been scarce owing to the poor ion stability and the problems of electric (corona) discharge, presumably caused by electrons emanating from the sharp edges of the ISP capillary needle held at a few thousand volts negative relative to a counterelectrode. The signal instability of electrospray ionization (ESI) can be reduced by adding chloroacetonitrile to the LC eluent, which acts as an electron scavenger, and there is a suppression of the electrical (corona) discharge phenomena leading to a stable ESI with finer charged liquid droplets. Nevertheless, the improvement in ion stability is obtained at the expense of sensitivity (one order of magnitude less) owing to the $[M + Cl]^-$ adduct ion formation and to the higher cluster ions intensity. Since the major analytical requirement of environmental analysis is to achieve a low DL, chloroacetonitrile is not commonly used.

6.4 Liquid Chromatography and Mass Spectrometry with Atmospheric Pressure Chemical Ionization

In APCI, the column eluent is pneumatically and thermally nebulized into an atmospheric pressure ion source. The APCI technique differs from ESP and ISP in that the spray is generated as a result of applying nitrogen gas and heat at the interface. The spray, which contains the mobile phase and the analytes, is subsequently ionized at the nebulizing chamber after applying a corona discharge of 2–4 kV. The analytes are ionized by gas-phase ion–molecule reactions (e.g. proton transfer). The ions formed, together with solvent vapor and nebulizing gas, are sampled towards the sample cone and into the mass spectrometer.

The main advantages of liquid chromatography coupled to mass spectrometry with atmospheric pressure chemical ionization (LC/APCIMS) over ESP/ISP is that ions do not have to be formed in solution and, therefore, compounds with a wider range of polarities and physicochemical properties can be determined. Another advantage is that more fragmentation is obtained with APCI than ESP/ISP and that sodium clusters rarely appear. As heat is applied in addition to pneumatic nebulization, some OPPs can be determined with APCI whereas they gave no signal under ESP/ISP. Moreover, in APCI, higher flow rates can be handled (up to 2 mL min^{-1}), which makes it easy to couple with conventional columns and with SPE switching techniques. In APCI, no buffer addition is required and, in contrast to TSP, no significant differences in sensitivity are observed when working at different ratios of water and organic modifier.

From the practical point of view, there are two main parameters to be optimized in APCI: the corona discharge voltage and the cone extraction voltage. For the corona discharge, a voltage between 2.5 and 3 kV is usually chosen, as at lower discharge voltages weak ionization is achieved and above 3 kV the ionization efficiency decreases dramatically. Similar to the ISP interface, by raising the cone voltage structural information can be obtained via CID. The advantage of APCI techniques is that analytical parameters can be varied to gain both in structural information and sensitivity. The pressure of the nebulizing and drying gas basically affects sensitivity. A study[141] has been published on the probe temperature and extraction voltage effect of the APCI interface on the fragmentation and sensitivity of several OPPs. Whereas the interface temperature has a major role in sensitivity and does not affect fragmentation, an increase in the extraction voltage produces more fragmentation, at the expense of sensitivity. It was found that at a 30 V extraction voltage, the best sensitivity was obtained for the majority of the OPPs studied, whereas 40 V produced the highest fragmentation, giving in most cases fragmentation patterns similar to those obtained with MS/MS. By increasing the cone voltage to 60 V, pseudomolecular ions of pesticides underwent strong fragmentation to the point that only diagnostic fragment ions were present in the CID spectra.[141] Pesticides of the parathion group underwent strong fragmentation at low extraction voltages, giving fragment ions with low m/z as base peaks. For these pesticides, there were no differences in the formation of fragment ions under cone voltages of 20 and 40 V, probably because an extraction voltage of 20 V was sufficient to fragment the molecules. Table 6 indicates the fragment

Table 6 Characterization of OPPs with LC/APCIMS and PI at extraction voltages of 40 and 20 V, with percentage of abundance of each ion and tentative identification

ions of several OPPs obtained by LC/APCIMS in the PI mode of operation with extraction voltages of 20 and 40 V. It can be observed that the fragmentation pattern differs in the two conditions and, in general, fragment ions of lower m/z values are formed at a 40-V extraction voltage.

Previous studies on OPP analysis with LC/APCIMS include those of Kawasaki et al.,[142] who obtained structural information under APCI conditions and DLs varying between 2 and 50 ng under SIM conditions. The optimization and validation of on-line SPE with LC/APCIMS for OPP analysis has been performed by Lacorte et al.,[30] who report DLs at the low nanograms per liter level and good recovery and reproducibility values. Figure 6(a–c) shows a typical chromatographic profile of a 100-mL groundwater sample spiked with pesticides at $1\,\mu g\,L^{-1}$ and analyzed under full-scan and SIM in PI and NI modes of ionization. An interesting feature of on-line SPE with LC/APCIMS is that it can be operated under full-scan conditions as an ''alarm'' system to detect organic contaminants in water samples, since pesticides are found in natural waters at levels between 1 and $10\,\mu g\,L^{-1}$. In general, DLs of OPPs are around $500\,ng\,L^{-1}$ in full-scan and $1–60\,ng\,L^{-1}$ in the SIM mode. The excellent sensitivity, even in the full-scan mode, combined with the abundant structural information provided by the APCI interface makes the technique suitable for the screening of pesticides in environmental samples in the parts per trillion to billion range. The APCI interface can also be used for structural elucidation studies. Several TPs of temephos and fenthion[143] were identified by increasing the extraction voltage of the APCI interface. At a 40-V extraction voltage, oxo analogues, sulfoxides and the isomeric forms of the above-mentioned pesticides were unequivocally identified. This means that in the near future, this technique can be implemented in routine work for the analysis of real water samples, since it can detect both parents and TPs of pesticides at the nanograms per liter level. However, more research is needed on the characterization of oxo analogues and other metabolites before optimal analytical conditions can be defined.

LC/APCIMS under NI normally generates $[M - H]^-$ ion or specific fragment ions as the base peak. The use of the NI mode permits the detection of most electronegative compounds and better selectivity and sensitivity are obtained. However, many OPPs can undergo strong fragmentation, even at a 20-V extraction voltage, and produce in some cases a single ion, which is often a diagnostic ion, so that compound elucidation is difficult.

In summary, future trends will lead to the more extensive use of API interfaces for environmental applications owing their high sensitivity and the possibility of obtaining structural information. However, the main operational problem with APCI and in general all API

interfaces arises from the high cleaning requirements of the sample cone and skimmer assembly, especially when dirty water samples are processed. However, it should be remembered that this is a common problem with most of the LC/MS interfaces currently available. To achieve maximum sensitivity in API techniques, the system should be calibrated very accurately, and therefore it is essential to have a clean interface. In API interfaces, the system response should be checked after every cleaning step, but even with a clean interface, reproducibility values above 25% are common. Better values are obtained if an internal standard is used.

7 VALIDATION OF ANALYTICAL METHODS

As a result of variations in the results reported by various laboratories, method testing, based on repeatability, reproducibility and calibration data, should be done routinely to evaluate the performance of an analytical method. Any analytical method should be precisely developed to provide reliable quantitative results. Therefore, validation becomes a key issue before method approval and implementation can be done. Any analytical method should provide statistical documentation of its capacity for rendering accurate results. In environmental chemistry, the achievement of an accurate determination is a challenge since (i) the analytes of interest are often at a very low concentration level, normally in the parts per trillion to billion range, (ii) environmental matrices can be very diverse and complex, from drinking and groundwater samples, which represent the easiest matrix, to surface or wastewater, which pose some problems of analysis owing to the presence of humic and fulvic material and other interferences; moreover, food and sediment samples also represent a problem in analysis, owing to the interfering matrix or sugar and fat content; and (iii) a highly efficient separation and detection technique is required to determine numerous isomers or congeners and compounds with different polarities and physicochemical properties. For such reasons, it is obligatory to use validated methods since more and more different laboratories need to compare the levels of OPPs in different matrices for QA purposes. To compare results, one has to prove that the method used is accurate and precise and that these parameters hold with time.

To test the performance and validate a method, certified reference materials are used. There are two main types of reference materials. The first type consists of high-purity mixtures of compounds of one chemical class dissolved in a pure organic solvent, and are used for calibration of the analytical system, for identification of the analytes and for spiking the samples, in other words, for method performance. The second type is used to asses the whole analytical procedure, from the extraction of the analytes to the final analysis, which is performed by participating in interlaboratory calibration exercises. The advantage of participating in interlaboratory exercises is that each laboratory can validate a new-sprung extraction and detection method by comparing it with well-known and established techniques, such as GC. Lacorte et al. reported the validation of SPE coupled on-line with LC/DAD, LC/TSPMS and LC/APCIMS for the analysis of OPPs in ground and wastewaters.[30,144] The established procedure for validating an analytical method includes the evaluation of several quality parameters, such as: (i) linearity of the detector for establishing the minimum and maximum concentrations that can be handled; (ii) DL, measured from the calibration curve and taking a signal-to-noise ratio (S/N) of 3 (it should be verified experimentally); (iii) the limit of quantification (LOQ), which is calculated taking an S/N of 10; (iv) precision or repeatability of the technique, which indicates the percentage error made in consecutive analyses, without changing any experimental conditions; for a standard injection, it should be 1–2%, and for a whole analytical procedure (e.g. analysis of waters) it can rise to 10%, which is the allowed error according to the USEPA; (v) reproducibility, or variation of the analytical response between-day precision, keeping all the experimental conditions equal; under controlled conditions (column oven, mobile phase, pH, etc.), the reproducibility should not be much higher than the repeatability, but in practice, it is seen that many MS detectors do not respond in the same way since the ionization efficiency can vary substantially in different days, and to avoid this problem one should work with internal standards; (vi) recoveries, which should be between 70 and 130% for the tested analytes, according to the USEPA; and (vii) accuracy or determination of the relative difference between the experimental value and the true value, which should be checked in interlaboratory calibration exercises.

To summarize, validation of analytical methods is important not only to prove the accuracy and reliability of an analytical method, but also to be able to compare results obtained in different laboratories. Validation is tedious but needs to be done.

8 CONCLUSIONS

The analysis of OPPs in water and food samples include three main steps: extraction, cleanup and detection. The present trend is the use of multiresidue, automated methods for the surveillance of pesticides and their degradation products in environmental samples. For water samples, LLE, which used to be the most

popular method, has been replaced by SPE, which has the advantage that it is less laborious, quicker, diminishes solvent consumption, can be used as storage media and produces more reproducible results. Both on-line and off-line SPE can be nowadays automated by sophisticated equipment such as the Prospekt, the OSP-2 and the ASPEC or Zymark, respectively. Since manipulation of the water sample is minimized, these techniques produce extremely precise and accurate results. Different types of packing materials for SPE (e.g. silica-based C_8 and C_{18}, styrene–divinylbenzene copolymeric materials, immunosorbents and MIPs) provide an extremely selective way to trap compounds of diverse physicochemical properties. The advent of immunosorbents or MIPs will certainly increase the efficiency of a selective extraction both from water and food samples and will minimize the sample cleanup.

Food samples represent a more complex matrix owing to their great versatility and the presence of fats and sugars. Food samples are freeze-dried and pesticides are extracted by Soxhlet or ultrasonic methods. Sample cleanup using GPC or column chromatography with Florisil, alumina or other sorbents is essential to eliminate matrix impurities. Generally, the analysis of food samples requires a high degree of manipulation and there is a need to optimize the analytical technique for each type of food matrix.

In all cases, sampling, transport and storage of the water or food samples should be carefully performed to avoid sample deterioration or degradation of the pesticides. Normally, samples are transported refrigerated and kept preferably at $-20\,^{\circ}C$.

Most commonly, OPPs are analyzed by GC, which is a well known and established technique for OPP monitoring and is the official method adopted by the USEPA. The high sensitivity of GC methods, together with the high separation efficiency and speed of analysis, favors multidimensional analysis and routine monitoring. GC with NPD and ECD are the most common techniques, and analysis has to be performed with two columns of different polarity or using MS detection. In this way, it is possible to confirm the presence of a pesticide in water or food samples. GC/MS methods are sensitive, selective and reproducible and offer structural information. GC/MS with EI produces abundant fragment ions and the analytes can be identified by library spectral matching whereas NCI gives molecular information and is more sensitive and selective for electronegative pesticides. The main disadvantage of GC is that it cannot handle polar, nonvolatile or thermolabile compounds without a previous derivatization step.

In the last few years, new technologies based on HPLC systems have been developed to determine organic pollutants in the environment. UV and DAD are the most common detection devices used for determining priority pesticides in water and food matrices. LC/DAD has the advantage that it gives a UV spectrum that can be used for identification and confirmation purposes. LC can be coupled to MS with different types of interfaces, such as PB, TSP and the recent API techniques. API interfaces have slowly replaced the others since they can produce abundant fragmentation by increasing the electrical field in the intermediate region of the mass analyzer so that CID spectra can be obtained by a single quadrupole. Compared with PB and TSP, API techniques are highly sensitive, with DLs at the picograms level, reproducible and have a linear range over various orders of magnitude. Moreover, provided an efficient preconcentration technique is applied, it is possible to quantify the analytes at the nanograms per liter level, similar to what is obtained with GC. As a consequence, LC/MS is becoming a highly robust technique and the preferred option for the identification and confirmation of OPPs in routine monitoring programs.

With regard to qualitative assurance, all the analytical techniques have to be validated in order to provide reliability of the results. This is important for qualitative control and to allow the comparison of the results provided by different laboratories. The analysis of certified samples is important in order to establish the accuracy of each method and it is necessary before a technique can be implemented in routine monitoring programs concerning OPPs.

ABBREVIATIONS AND ACRONYMS

AED	Atomic Emission Detector
APCI	Atmospheric Pressure Chemical Ionization
API	Atmospheric Pressure Ionization
CEC	Commission of the European Communities
CI	Chemical Ionization
CID	Collision-induced Dissociation
DAD	Diode-array Detection
DL	Detection Limit
ECD	Electron-capture Detector
EI	Electron Ionization
ESI	Electrospray Ionization
ESP	Electrospray
ESP/ISP	Electrospray/Ionspray
ESP/ISPMS	Electrospray/Ionspray Mass Spectrometry
EU	European Union
FID	Flame Ionization Detection
FPD	Flame Photometric Detection

GC	Gas Chromatography
GCB	Graphitized Carbon Black
GC/FID	Gas Chromatography/Flame Ionization Detection
GPC	Gel Permeation Chromatography
GUS	Ground Ubiquity Score (Mobility Index)
HPLC	High-performance Liquid Chromatography
HPN	Heated Pneumatic Nebulizer
IDL	Instrument Detection Limit
IS	Immunoaffinity Sorbent
ISP	Ionspray
LC	Liquid Chromatography
LC/APCIMS	Liquid Chromatography Coupled to Mass Spectrometry with Atmospheric Pressure Chemical Ionization
LC/DAD	Liquid Chromatography with Diode-array Detection
LC/ESP/ISPMS	Liquid Chromatography Coupled to Electrospray/Ionspray Mass Spectrometry
LC/MS	Liquid Chromatography with Mass Spectrometric Detection
LC/TSPMS	Liquid Chromatography Coupled to Mass Spectrometry with a Thermospray Interface
LC/TSPMS/MS	Liquid Chromatography Coupled to Tandem Mass Spectrometry with a Thermospray Interface
LLE	Liquid–Liquid Extraction
LOQ	Limit of Quantification
LSE	Liquid–Solid Extraction
MIP	Molecular Imprinted Polymer
MS	Mass Spectrometry
MS/MS	Tandem Mass Spectrometry
NCI	Negative Chemical Ionization
NI	Negative Ionization
NPD	Nitrogen-phosphorus Detector
OPP	Organophosphorus Pesticide
PB	Particle Beam
PCI	Positive Chemical Ionization
PGC	Porous Graphite Carbon
PI	Positive Ionization
QA	Quality Assurance
QC	Quality Control
SEC	Size-exclusion Chromatography
SFE	Supercritical Fluid Extraction
SIM	Selected Ion Monitoring
S/N	Signal-to-noise Ratio
SPE	Solid-phase Extraction
SSC	Single Short Column
THF	Tetrahydrofuran
TSP	Thermospray
TP	Transformation Product
UCM	Unidentified Complex Matrix
USEPA	United States Environmental Protection Agency
USNPS	United States National Pesticide Survey
UV	Ultraviolet

Miscellaneous pesticides and related compounds include the compounds that can neither be included in the classical chemical category of pesticides nor classified by their class of action. They are a heterogeneous group of substances like macrocyclic lactones, chloronicotinyls, tetranortriterpenoids, ammonium quaternary salts, dinitroanilines, acetamides, oximes, triazoles and pyridine-based molecules. Their common characteristic is that they are recently developed pesticides. Sample preparations in environmental matrices: air, water, soil, food and biological samples are described. Analytical techniques for characterizing these compounds include gas chromatography (GC), high-performance liquid chromatography (HPLC), and a wide variety of other emerging techniques such as capillary electrophoresis (CE), supercritical fluid chromatography (SFC), voltammetric and immunoassay techniques. Here, those applied to the field of real samples are presented.

1 INTRODUCTION

Environmental management depends on information on a wide range of compounds. Unreliable or inaccurate information may lead to large economic losses which are caused, for example, by sanitation measures that are not needed, or to unacceptable risk to the environment or human health if necessary measures are not taken.

Method development within environmental areas is of great importance in helping to obtain the selectivity and sensitivity necessary for monitoring low levels of toxic substances as required by environmental regulations. Analytical techniques that fulfil these requirements can be achieved by the use of chromatographic separation steps coupled with selective sample handling techniques. In these steps, the pesticides are separated from the many matrix substances and simultaneously enriched. Goals are also reached by striving for more selective detection principles and techniques, such as mass spectrometry (MS) combined with GC or HPLC. Immunoassays offer certain advantages over conventional instrumental methods for the analysis of pesticide residues and are ideally suited for screening a large number of samples for low levels of specific analytes.

New groups of pesticides have been invented for plant protection at low doses, with a reversible mode of action, less persistence, systemic action and adequate potency against crop pests. A critical review of the analytical methodology used to determine these newly developed pesticides is required so that the methods of analysis evolved for the generation of data can be used as standards.

2 DESCRIPTION

There are many registered chemicals that can be included under the heading of miscellaneous pesticides and related compounds which comprise a large group of substances with very different characteristics and applications.[1] Their common attribute is that they do not belong to the classical chemical categories of pesticides, such as organochlorines, organophosphates, carbamates or triazines.[2] However, depending on their chemical structure they can be classified into several chemical classes, the most important of which are macrocyclic lactone, chloronicotinyl, tetranortriterpenoid, ammonium quaternary salt, dinitroaniline, acetamide, oxime, triazole and pyridine-based molecules. Table 1 shows the chemical structures and some examples of the major classes that could be considered to be miscellaneous pesticides.

The avermectins are macrocyclic lactones produced by the soil microorganisms *Streptomyces avermitilis*. Two avermectins have been commercialized to date. The semisynthetic 2,2,2,2,3-dihydroavermectin B_1 known as ivermectin is used as an antiparasitic drug in animals and man; avermectin B_1, known as abamectin, is widely used as an insecticide and miticide for agricultural crops.[3]

The chloronicotinyl insecticides act on cholinergic receptors and have good contact properties and powerful systemic action after uptake through the root system. They are effective in controlling aphids, whiteflies, thrips, scales, psillids, plant bugs, leafhoppers, planthoppers, and other harmful pest species including resistant strains. Owing to their insecticidal effectiveness at low concentrations and their safety in the environment, the chloronicotinyls are seen as promising newcomers.[4]

Azadirachtin is a tetranortriterpenoid (limonoid) present in neem seeds (*Azadirachta indica* A. Juss). Azadirachtin has gained worldwide attention for its insect antifeedant and ecdysis-inhibiting properties. This compound is highly potent at low concentration against more than 200 agricultural pests and it is ecofriendly. It is therefore a potentially safe alternative to the toxic synthetic pesticides and a number of commercial formulations have been introduced worldwide.

The bipyridylium herbicides DQ, PQ and DF are important cationic pesticides used in agriculture. They are usually supplied as dibromide, dichloride and methyl sulfate salts, respectively. They are nonselective contact herbicides that are absorbed by foliage with some translocation though the xylem. They are used for the broad-spectrum control of broad-leaved weeds and grasses in fruit orchards, plantation crops, ornamentals and shrubs. They are also applied for general weed control on noncrop land and have been recommended for the control of aquatic weeds. They have been applied as defoliants on crops such as cotton and as desiccants for pineapples, potatoes, sugarcane and sunflower. CQ and MQ chloride are cationic plant growth regulators, structurally related to the bipyridylium herbicides, which are mainly used to prevent loging in barley and rye and also to increase the yield of cotton.

Dinitroanilines are selective pre-emergence herbicides used to control some broad-leaved weeds and the major annual grasses in a wide variety of agronomic crops. They disrupt mitosis in the meristematic cell of seedling plants by inhibiting the formation of microtubules.

The group of acetamide pesticides (some also known as chloroacetamides) encompasses a considerable number of herbicides and fungicides used to control weeds and fungi in crops. The compounds are widely used to control annual grasses and certain broad-leaved weeds in corn, soybeans and peanuts and to control phytopathogenic fungi (*Peronosporales*) in potatoes, sugar beets, and other crops. They act by inhibiting protein synthesis by reaction of the activated Cl atom of the chloroacetyl group with reactive sites in proteins.

Oximes are bioactive compounds, originally discovered in insects, that have recently been synthetized, and some are effective herbicides.[5]

Triazole derivatives are aromatic heterocycles widely used as weed killers, fungicides, insecticides, plant growth regulators and antimicrobial agents.[6] They are nonselective systematic herbicides used against a wide variety of plants.

Pyridine-based molecules are a group of substances that include pyridazines, pyridazones and pyridones. All of them are herbicides but their applications vary. For example, Pyridate is a pyridazine that acts by contact while pyridazone derivatives such as norflurazon and cloridazon are soil-applied herbicides and fluridone, a pyridone, is an experimental herbicide developed for aquatic plant management systems.

3 CHARACTERISTICS

3.1 Physical and Chemical Properties

In order to develop the best residue analytical methods with the most appropriate instruments, a knowledge of the physical and chemical properties of the pesticides is essential. For example, it is impossible to develop a GC residue method for imidacloprid without derivatization because of the very polar and nonvolatile properties displayed by this molecule. Similarly, a direct GC method for DQ, PQ or azadirachtin is also impossible because of the polarity of these compounds. The physical and chemical properties of some typical herbicides are shown in Table 2.

Table 1 Class of compounds, typical examples and structures included as miscellaneous compounds

Class	Typical examples	Chemical structure
Macrocyclic lactone	Avermectin Ivermectin Emamectin	 Avermectin
Chloronicotinyl	Imidacloprid Acetamiprid	 Imidacloprid
Tetranortriterpenoid	Azadirachtin	Ammonium quaternary salt	DQ PQ DF CQ MQ	 Paraquat
Dinitroaniline	Butralin Dinitramine Ethalfluralin Oryzalin Pendimethalin Trifluralin	 Pendimethalin
Acetamide	Alachlor Acetochlor Metalaxyl Metolachlor	 Acetochlor
Oxime	Alloxydim Clethodim Sethoxydim	 Clethodim
Triazole	Amitrole Carfentrazone ethyl Fenchlorazol ethyl Flupoxam	 Amitrole
Pyridine-based molecule	Chloridazon Thiazopyr Norflurazon Fluridone Pyridate	 Fluridone

DQ, diquat; PQ, paraquat; DF, difenzoquat; CQ, chlormequat; MQ, mepiquat.

Table 2 Physical and chemical properties of some miscellaneous compounds

CAS number	Pesticide	Molecular weight	Appearance	Mp (°C)	Vapor pressure (20–25 °C)	Solubility				LogP_{ow}

The avermectins are a family of macrocyclic lactones. Abamectin is a mixture of two components. The major one is avermectin B_{1a}, which makes up 80% or more of the mixture, and the minor component is avermectin B_{1b}, which supplies 20% or less; the two components differ in a single methylene group.[7] Ultraviolet (UV) light below 280 nm rapidly isomerizes the *E* (*trans*) 8,9 and 10,11 double bonds of avermectin to 8,9- and 10,11-*Z* isomers. However, solutions of avermectin in Pyrex flasks are generally stable because Pyrex excludes most of the UV light below 280 nm. Avermectin residues degrade rapidly by both oxidative and photochemical pathways, forming a variety of products when applied to a number of different crops. Therefore, the only residues of toxicological significance are avermectin and 8,9-*Z* avermectin.[8]

Ivermectin is synthesized from avermectin by reducing the 22,23-double bond, thus producing dihydroavermectin B_{1a} and dihydroavermectin B_{1b}. These compounds are notable for their potent anthelmintic and insecticidal activities.

Emamectin benzoate (MK-224, MAB_1 benzoate, 4-deoxy-4-epimethylamino avermectin B_1) is a derivative of abamectin and consists of two avermectin homologs, each with a molecular weight of approximately 900. By specification it consists of at least 90% 4″-deoxy-4″-epimethylaminoavermectin B_{1a} benzoate and not more than 10% of 4″-deoxy-4″ epimethylaminoavermectin B_{1b} benzoate. These components differ only in a methylene group on the C-25 side chain. Emamectin benzoate is an effective insecticide against lepidopteran larvae and is currently under development for use on a number of crops including celery, lettuce, cabbage and tomato.[9] Emamectin benzoate is an ionizable salt and displays higher water solubility than other avermectins,[10] but binds very tightly to topsoil and is, therefore, immobile.[9]

Soil biodegradation studies on the chloronicotinyl imidacloprid have demonstrated that its major metabolite is 6-chloronicotinic acid, and that it leaves no soil residue after the first 3 months.[11] Acetamiprid is stable in solution at pH between 4.5 and 7. It is slowly degraded at pH 9 and 45 °C.

Azadirachtin is nonvolatile and highly polar. It has UV absorption due to the α,β-unsaturated carbonyl chromophore in the ligate ester and the vinyl ether, but the absorption maximum is at a very short wavelength.[12] Azadirachtin hydrolyzes readily at 35 °C, and its disappearance follows simple pseudo-first-order kinetics. Its hydrolysis is faster at a basic than an acidic pH.[13]

DQ is marketed as a dibromide and dibromide monohydrate salts and as a base. PQ is marketed as a chloride and dimethyl sulfate salts and DF is marketed as methyl sulfate salts.[14] The PQ salts are hygroscopic, not volatile and very soluble in water. PQ is extremely stable in the presence of acids but it is destroyed quickly in a basic medium. It is soluble in water and insoluble in organic solvents. DQ is also very thermostable and not volatile.[15] The herbicide activity of PQ and DQ is related to the planar structure of their molecules and the 18 possible resonant structures that stabilize the radical formed in reduction reactions in which they are involved.[16] DF salts are very soluble in water and are stable to hydrolysis.[17] DF is stable at weakly acid pH but is degraded in strong acids and in the presence of oxidizers. The three herbicides present an absorption band in the UV at 260, 310 and 255 nm, respectively, due to the presence of aromatic rings in their structures.

Although the dinitroaniline herbicides are chemically related, they differ in volatility, persistence in soil and absorption by crops, and for this reason may differ in their effects on soil, plants and air. These compounds are among the least mobile herbicides, and therefore runoff is the principal route of the contamination of surface waters.[18] Dinitroaniline herbicides are water insoluble, relatively volatile and strongly adsorbed to soil colloids. In soil, both chemical reactions and biological processes degrade pendimethalin. In general, dinitroaniline herbicide degradation is more rapid under flooded anaerobic conditions than under aerobic ones.

Acetamide herbicides have moderate water solubility and are rapidly absorbed into plants. In susceptible plants, the herbicides act by inhibiting protein synthesis, whereas insensitive plants rapidly inactivate these herbicides via gluthathion conjugation. In sensitive fungi, the structurally related fungicides have effects on RNA synthesis. As these reactions involve various chiral structures, some stereoselectivity is expected in the activity of these compounds.

Oximes are bioactive compounds originally discovered in insects. Field trials with these compounds showed that they were not consistently effective, perhaps because of the instability of this active ingredient. Sethoxydim undergoes degradation, including photodegradation. Clethodim is also degraded in aqueous solution by acid medium and light. Clethodim degradation increases as solution pH decreases and photolysis is more rapid and more complete than hydrolysis.[5]

Amitrole belongs to the triazole group[19] and is soluble in water, methanol, ethanol and chloroform, slightly soluble in ethyl acetate and insoluble in ether and acetone. Aqueous solutions are neutral.

Pyridate is a colorless crystalline solid that melts at 27 °C and boils at 220 °C under 10^{-6} mbar vacuum. Its vapor pressure is 1.3×10^{-9} mbar at 20 °C. It is stable in neutral medium, but is hydrolyzed in strong acid and strong alkali media.[20]

3.2 Toxicology

Pesticide residues are regulated at the international and national level according to the toxicity of the pesticide and the human exposure to a particular substance. Table 3 lists the acute oral and dermal toxicity for different animal species, chronic toxicity for dogs, and the ADI.

The macrocyclic lactones are neurotoxins that manifest their action by disrupting the normal function of γ-aminobutyric acid (GABA), an important neurotransmitter in the central nervous system of vertebrates and in the peripheral nervous system of invertebrates. Because mammals only have GABA ergic synapses in the central nervous system, the mammalian blood–brain barrier ensures a degree of specificity. A notable feature of this group of compounds is their low LD_{50} (lethal dose 50) values, but they are not usually highly toxic by the dermal route on account of their large molecules and poor transdermal absorption. In vitro studies with preparations of rat brain have shown that avermectin B_{1a} stimulates presynaptic binding of GABA and enhances postsynaptic binding of GABA; the action of avermectin B_{1a} is antagonized by bicuculline and picrotoxin.[21]

Avermectin and ivermectin are metabolized in a qualitatively similar way among different species. The major metabolites of both in cattle, sheep, swine and rats are either 24-hydroxymethyl or 3″-*O*-desmethyl derivatives. However, the enzymes responsible for the metabolism have not been identified in any species.[7] These compounds undergo little metabolism and most of the dose given to the animal is excreted relatively unaltered, primarily in the feces.[3] Abamectin induces teratogenic effects such as cleft palate.

The chloronicotinyl insecticides interfere with neuronal functions as do organophosphate, carbamate and pyrethroid insecticides. Unlike the latter pesticides, they act on nicotinergic acetylcholine receptors on the

NOEL, no observable effect level; ADI, admissible daily intake.

postsynaptic membrane of an identified insect motor neuron.[11]

Azadirachtin is nonmutagenic and does not appear to exhibit mammalian toxicity.[22]

PQ toxicity in both experimental animals and humans targets primarily the lung, whereas DQ does not. It is believed that the differences between PQ and DQ are a result of the fact that the lung selectively accumulates PQ and not DQ. PQ-induced pulmonary injury takes place in two phases: destructive and proliferative. It has been suggested that the biochemical reactions that lead to the destructive effect of PQ are analogous to its toxic action on plant cells. NADPH (nicotinamide adenine dinucleotide phosphate (reduced form)) is the donor for the single-electron reduction of PQ. Reduced PQ is reoxidized rapidly by molecular oxygen and superoxide radicals are formed. The superoxide radicals initiate a chain of reactions that produce toxic reactive intermediates that include hydrogen peroxide and hydroxy radicals and also produce lipid peroxidation. They are responsible for the disruption of cellular membranes. In addition, PQ competes for and deprives other systems of essential NADPH and compromises their cellular integrity.[23,24]

DQ poisoning differs from that of PQ in that the renal effects are more prominent and lung changes do not generally occur. An effect of DQ that has been extensively investigated is its ability to produce cataracts in experimental animals.[23] PQ produces chronic effects such as costal cartilage malformation in rats when injected during the gestation. It appears that the teratogenicity of PQ results from its effect on collagen biosynthesis.[24]

CQ is known to be a competitive inhibitor of cholinesterase in animals. This anticholinesterase chemical causes acetylcholine accumulation at cholinergic receptor sites and thus is capable of producing effects equivalent to excessive stimulation of cholinergic receptors through the central and peripheral nervous system.[25]

Substituted anilines have the general property of causing methemoglobinemia, as do many other aniline derivatives. The probable mechanism of methemoglobinemia is N-hydroxylation to the corresponding hydroxylamine, which then takes part in an intraerythrocytic cycle with the corresponding nitroso derivative generating methemoglobin at the same time. Alachlor is classed as a probable human carcinogen by the USEPA (United States Environmental Protection Agency)[26] because of its carcinogenic effect on rodents, where it produces posterior nasal and stomach tumors, possibly by a nongenotoxic mechanism.

Little is known of the human metabolism of amitrole but experiments with [^{14}C]amitrole orally administered to rats show that 80–90% of the compound is excreted unchanged in the urine.[27] The International Association for Research on Cancer (IARC) classifies amitrole as a possible human carcinogen that produces thyroid tumors apparently through an indirect mechanism. Amitrole inhibits thyroid peroxidase, thus lowering the thyroxin level. The thyroid gland becomes hyperplasic and eventually forms tumors.

The literature is scarce on toxicity of the oximes. There are only a few studies demonstrating that sethoxydim produces lesions in bone marrow and the liver of dogs.[28]

In laboratory metabolism studies with ^{14}C-fluridone, a major fluridone metabolite, 1-methyl-3-(4-hydroxyphenyl)-5-[3-(trigluoromethyl)phenyl]-4-(1*H*)-pyridinone was present in bluegill and fathead minnows at levels equivalent to 50% and 15% of the total residue in fish, respectively.

3.3 Regulations

A legal tolerance is defined as the maximum level or concentration of a pesticide, or its metabolites or derivatives, that is permitted in or on a particular food crop or food product. The amount is generally no higher than the concentration present in or on a particular food crop or food product as a result of good agricultural practices.

The European Union (EU) has proposed rigid limits for pesticides in drinking water, especially 0.1 $\mu g\,L^{-1}$ (0.1 ppb) for a single pesticide and 0.5 $\mu g\,L^{-1}$ (0.5 ppb) for total pesticides including their degradation products.[29] In the United States, USEPA has set values for maximum contaminant levels for pesticides individually. The USEPA values range approximately from 1 $\mu g\,L^{-1}$ to 1 mg L^{-1} (1 ppb to 1 ppm).[30,31] Such levels are more specific than EU levels, which are fixed for all the individual pesticides without making any distinction between individual pesticides of different toxicity.[32] However, of all the pesticides covered in this article, USEPA has only established a health advisory level of 20 $\mu g\,L^{-1}$ for DQ.[31]

The maximum levels of these miscellaneous pesticides in fruit and vegetables allowed in the EU are shown in Table 4.[33–36] Maximum levels in animal tissues, other biological samples or different environmental compartments have not been established. These established tolerances are revised periodically and the tendency is to diminish the permitted levels. This fact poses substantial analytical problems and demands a methodology of greater sensitivity.

4 ISOLATION OF THE SAMPLE

4.1 Macrocyclic Lactones

Abamectin has been determined in ambient air and on surfaces following their treatment with the pesticide. Surface sampling was performed with cotton dosimeters

with or without wetting solutions such as 2-propanol. Air sampling is achieved in Teflon™ filters or in Orbon™ 42 tubes. Teflon™ air filters and cotton dosimeters were extracted with acetonitrile using amber jars or Soxhlet™. Cleanup was done by diluting with the ionized water passing through octyl (bonded C_8) and amipropyl ($-NH_2$) solid-phase extraction (SPE) columns.[37,38]

Emamectin benzoate was concentrated from water on C_8 SPE cartridges and eluted with acetate ammonium in methanol.[10]

The methods described for the determination of macrocyclic lactones from vegetables require complicated homogenization/extraction schemes. Fruit and vegetables are mainly extracted with acetonitrile/water/hexane (1 : 1 : 5). Abamectine and its δ 8,9-isomer are concentrated by passing the hexane layer through an aminopropyl SPE cartridge.[39–43] Lettuce and cucumber are extracted with ethyl acetate and the extract is purified by SPE using a Sep-Pack™ silica cartridge.[44] Emamectin benzoate is extracted from lettuce and celery with methanol, and the extract is cleaned up on a C_8 cartridge followed by LLE (liquid–liquid extraction) with ethyl acetate before passing through a propyl sulfonyl cation-exchange cartridge.[45]

Abamectin residues from soil samples have been extracted with acetonitrile.[9,21] The insecticide abamectin is extracted from soil and animal tissues using supercritical-fluid extraction (SFE).[46] Supercritical carbon dioxide

Table 4 Miscellaneous pesticides tolerance in fruit and vegetables[33–36]

Pesticide	Residue	MRL (ppm)
Abamectin	Total toxic residue includes parent abamectin and its δ 8,9-isomers	0.01
Imidacloprid	Sum of imidacloprid and its major metabolite 6-chloronicotinic acid expressed as 6-chloronicotinic acid.	Citrus fruits 1 Seed fruits, apricot, peach, nectarine and paprika 0.5 Tomato, cucumber, gherkin and marrow 0.1 Other products 0.05
DQ	Sum of DQ and its dibromide expressed as ion DQ	Cotton seeds 0.5 Vegetables and sunflower seeds 0.1 Other products 0.05
PQ	Sum of PQ and PQ dichloride expressed as ion PQ	Tea 0.1
DF	–	Grain straw 3 Other products 0.1
CQ	Sum of CQ and its chloride expressed as ion CQ	Grain straw 10 Pear, rye and oats 3 Grape, raisin and wheat 1 Other products 0.05
MQ	–	Cotton seeds 0.5 Grain 0.3 Garlic 0.1 Other products 0.05
Butralin	–	Tobacco 5 Citrus fruit, seed fruits, artichoke, garlic, eggplant, onion, strawberry, soya beans, bean, paprika, tomato, carrot and cotton seed 0.1 Other products 0.1
Dinitramine	–	All products 0.01

Oryzalin	–	All products 0.01
Pendimethalin	–	All products 0.05
Trifluralin	–	Carrot 1 Other products 0.05
Alachlor	Sum of alachlor, 2,6-diethylaniline and its 1-hydroxyethyl, expressed as alachlor	Corn and sorghum foragers 0.5 Onion, species of genus Brassica, oleaginous seeds, and corn 0.1 Other products 0.05

(*continued overleaf*)

Table 4 (*continued*)

Pesticide	Residue	MRL (ppm)
Acetochlor	–	All products 0.01
Metolachlor	–	All products 0.05
Alloxydim-sodium	Sum of Alloxydim, its sodium salt and its analogous deallyloxydate (CM-l), expressed as alloxydim	Fruit and pepo vegetables, species of genus Brassica, lettuce, spinach and similars, watercress and endive, other aromatic herbs, fresh green leguminous, other young stem and mushrooms 0.5 Strawberries and beet leaves 0.2 Tubers and bulbs, onion seedling, fennel, leek, seed of sesame and sunflower, potato, alfalfa and other leguminous and legumes 0.05 Roots and sugar beet 0.02 Other products 0.01
Clethodim	Sum of clethodim and its hydroxylate metabolites, expressed as clethodim	Soya bean 0.3 Tomato, fresh green leguminous and seeds of flax, colza and cotton 0.1 Other products 0.05
Sethoxydim	Sum of sethoxydim and its main metabolites expressed as sethoxydim	Roots (except carrots), tubers, bulbs, fruits and pepo vegetables, Brassica, leaf vegetable and fresh aromatic herbs, fresh green leguminous, young stem and mushroom 0.5 Other products 0.1
Amitrole	–	Tea and dry hop 0.1 Other infusions 0.1 Fresh, desiccated or raw, frozen and without sugar fruits, nuts, fresh or raw, frozen or desiccated, legumes, oleaginous seeds and potato 0.05 Other products 0.05
Fenchlorazol ethyl	–	All products 0.05
Chloridazon	–	Beet leaves 0.5 Beet, spinach and similars 0.1 Other products 0.05
Thiazopyr	Sum of thiazopyr and its nitrile and amide derived thiazolic ring	Seed fruits 0.2 Other products 0.02
Norflurazon	Sum of norflurazon and demethylnorflurazon, expressed as norflurazon	Citrus fruits, seed fruit 0.1 Other products 0.05
Pyridate	–	All products 0.2

MRL, maximum residue limit; CM-l, methyl 5-(l-aminobutylidene)-2,2-dimethyl-4,6-dioxocyclohexanecarboxylate.

modified with 9% 2-methoxyethanol extracts abamectin from soil samples without the need for cleanup. Abamectin is also easily extracted from animal tissues without interfering coextractives.

Fish tissues have been extracted with acetone/methylene chloride and cleaned up with aminopropyl cartridges.[47] A simple specific procedure for determining avermectin B_1 in biological samples has been described[48] and is based on the development of a specific antiavermectin B_1 immunosorbent. Avermetin B_1 is extracted from cattle plasma, cattle meat and pear samples. The extracts are cleaned up on a SPE column (C_{18}) and an immunoaffinity column. Recoveries of avermectin B_1 from samples spiked at levels of 6 and 60 ppb ranged from 80–86%, with coefficients of variation of 5–14%. Feces samples are extracted with an acetone–water mixture, partitioned with isooctane and cleaned up with a C_{18} cartridge.[49]

4.2 Chloronicotinyls

To quantify imidacloprid in liquid and solid formulations samples were extracted in solvent or dissolved in acetonitrile.[50] Water samples were extracted with C_{18} SPE.[51] For extraction in vegetables, the acetone–dichloromethane extraction followed by a cleanup step on a C_{18} cartridge system is selected owing to the good recovery values.[52] Rice and cucumber are extracted with acetonitrile–water (80 : 20) and silica gel

column chromatography.[4] Soil samples are shaken with acetonitrile–water,[4,51] acetonitrile–methanol–water[11] or with chloroform.[53]

Acetamiprid in crops has been extracted with methanol, cleaned up by liquid–liquid partition with *n*-hexane or dichloromethane, and Florisil™ column chromatography used to remove interferences.[54,55]

4.3 Tetranortriterpenoids

Azadirachtin has only been determined in insecticidal formulations of kernel extract. Neem seed powder has been extracted by chloroform in a percolator[56] or by hexane in a Soxhlet™.[57] Insecticide formulations were dissolved in methanol–water (90 : 10) and C_{18} SPE was used to retain unwanted material.[22] SFC has also proven to be a suitable system for determining azadirachtin in crude extracts of neem.[12,58]

4.4 Ammonium Quaternary Salts

Water samples containing more than $1\,\mu g\,mL^{-1}$ can be analyzed directly.[14,59,60] The determination of trace amounts of DQ, PQ and DF in natural and drinking waters requires a preconcentration step before the HPLC determination. SPE techniques are frequently used with C_{18},[61] C_8,[62] silica,[17,63–65] graphitized carbon black (GCB)[66] and ion-exchange column chromatography.[59,67,68] Water sample treatment by isotachophoresis,[69] electrodialysis[70] and flow-injection analysis (FIA)[71–73] has also been reported.

Traditional methods of determination in fruit and vegetable crops include matrix maceration with acid solution and isolation with silica columns[16,74–77] or cation exchange resin.[78] DQ and PQ can also be isolated after derivatization and LLE with diethyl ether.[79] The separation of MQ after acid maceration can be carried out by partition with hexane followed by a cation exchange column.[80] DQ and PQ can be analyzed in edible oil after sonication with a phosphate buffer and cleanup with C_{18} cartridges.[81] CQ has been extracted from crops by maceration with methanol and after concentration, partitioned with hexane prior to alumina cleanup.[82]

Methods of determination in soil are similar to those reported for fruit and vegetables and involve matrix maceration with acid solution and isolation with cation exchange resin[78] or by partitioning with dichloromethane.[15]

Several methods are available for measuring DQ and PQ in biological fluids. DQ determination in blood serum and urine is performed directly after precipitating out the proteins and filtration.[78,83–85] DQ and PQ have been extracted using ion-pair extraction into organic solvents[86–90] and ion-pair SPE, using disposable cartridges of C_{18}.[91] The latter method is rapid, easy to perform and provides high recovery values. Cianopropyl extraction columns[92] or silica columns[93] have been applied to determine DQ and PQ in human samples (blood, urine, milk) by direct SPE. Simultaneous determination of PQ and DQ in tissues is achieved after homogenization with perchloric acid.[94] If further cleanup is required, the mixture is centrifuged and after adjusting the pH of the supernatant is passed through C_{18} cartridges.[95,96]

4.5 Dinitroanilines

Formulations containing benefin and trifluralin have been extracted in hexane.[97] Dinitroaniline herbicide concentrations in soil and plants have usually been measured after sample extraction with an organic solvent and purification using Florisil™ cartridges[98] or glass chromatography columns packed with Florisil™.[99,100]

A method based on the extraction of soil samples in small columns has been used to determine dinitroanilines. Acetone/water (90 : 10) was used for the extraction of simazine. Pendimethalin is extracted from soil with an extraction solution containing acetonitrile, water and glacial acetic acid and partitioning with *n*-hexane.[101]

Simultaneous determination of the dinitroaniline herbicides dinitramine, ethalfluralin, trifluralin, pendimethalin and isopropalin in soil and surface water has been reported.[18] The soil was extracted with diethyl ether and analyzed without any cleanup. The water was analyzed after purification and concentration on C_{18} cartridges.

4.6 Acetamides

Acetamide herbicides have been isolated from river water and rain samples by SPE with C_{18},[102–111] styrene–divinyl benzene copolymer,[112] XAD-2 resin,[113] carbon black[114] or by LLE with dichloromethane[115–117] or hexane.[26]

Acetamides in crops have been determined after extraction of metabolites obtained by hydrolysis. The anilines were isolated by steam distillation and partitioned with Superclean™ ENVI-Chrom P.[118–120] Soil was extracted with ethyl acetate[120] or with methanol–water (9 : 1) followed by SPE with C_{18}.[111] SFE was applied for the detection of herbicides in meat samples[121] and soil samples.[122,123]

4.7 Oximes

Few analytical methods have been reported for extracting and concentrating oxime herbicides from different matrices. An analytical method for the total content of alloxydim-sodium herbicide and its degradation products

in groundwater has been developed based on concentration by evaporation of water and ethyl acetate partitioning after derivatization of the analytes with H_2O_2.[124] Residue analysis of the herbicide sethoxydim and its major active metabolite was also performed in rapeseed.[125] The extraction procedure was based on celite–methanol extraction, which requires complicated partitioning mainly with $CHCl_3$. Recoveries ranged from 83 to 102%.

4.8 Triazoles

Commercial samples of amitrole have been analyzed.[19] The samples used were ''Compo-Total-Unkrautvernichter'' from Compo GmbH (composition: 10% amitrole, 25% simazine, 25% diuron) and ''Domatol Speziall'' (composition: 38% amitrole, 16% MCPA (4-chloro-2-methyl(phenoxy)acetic acid), 19.5% simazine) obtained from a plant protection office in Trier, Germany. The determination can be performed directly with solutions of the commercial herbicide formulations.

The difficulty of determining aminotriazole at trace levels in water is linked to the necessary extraction and concentration from the aqueous media. LLE or SPE cannot be performed with the classical sorbents owing to the low solubility of aminotriazole in organic solvents and its high solubility in water.[126,127] Since aminotriazole is ionized at a low pH, an ion exchanger can be used to extract it from water.[126,128] However, the effect of the inorganic cations causes rapid breakthrough in drinking water. It is also possible to use an ion-pairing preconcentration.[126,128] However, the most reported method for concentrating this compound is evaporation of water.[126,129,130]

In spite of all the above, a fast method for the determination of amitrole in drinking and groundwater has been reported.[131] Amitrole is separated from other substances by HPLC with a coulometric electrode array detector. Tap and well water with concentrations down to 0.1 μg amitrole L^{-1} can be determined without any enrichment step using this method. An HPLC method for direct determination of amitrole in urine has also been described[27] based on derivative formation.

Determination of amitrole in tissues has been performed after extraction of the material with methanol. The cleanup procedure includes chromatography on aluminum oxide and gel permeation chromatography to eliminate hydrophilic substances.[132] The average recovery is 80%.

Amitrole has been extracted from plant tissues and sandy soils with ethanol, adsorbed on a resin and desorbed with ammonia.[133] After acetylation with acetic anhydride and cleanup over a Sep-Pack™ silica cartridge, the amitrole-acetyl derivative is determined by GC. The average recoveries are between 81 and 96%.

4.9 Pyridine-based Molecules

A study comparing two SPE extraction methods for the analysis of thiazopyr and its monoacid metabolite in groundwater has been reported.[134] One of the methods is based on SPE with C_{18} extraction disks and the other with GCB. Recovery studies indicate excellent recovery percentages for thiazopyr and thiazopyr monoacid by both methods.

Thiazopyr residues have also been determined in soil, grass weed and seedlings of woody plants by GC. The herbicide was extracted from soil and plant samples with ethyl acetate and plant extracts were cleaned up on a Florisil™ column.[135] The average recoveries were always higher than 97% with a relative standard deviation between 1 and 6%.

A method has been presented for determining the aquatic herbicide fluridone.[136] Samples are passed through a Sep-Pack™ C_{18} cartridge to extract fluridone and eluted with methanol. Recoveries averaged 98%.

Residue methods for determination of fluridone in meat, milk, eggs, crops, fish and crayfish have also been described.[137,138] Fluridone is extracted from meat, eggs, crops, fish or crayfish with methanol, and the herbicide is extracted from milk with a disposable C_{18} cartridge. Extracts are purified by liquid partitioning and/or alumina column chromatography.[137,138] When the metabolite of fluridone is determined together with the parent compounds, the methanolic extracts are subjected to acidic hydrolysis to release the conjugated forms of fluridone and the metabolite.[138]

Norflurazon and its initial metabolite in soil have been determined. The method consists of soil sample extraction with methanol. Recoveries from fortified soils were >90% for norflurazon and >80% for desmethylnorflurazon.[139]

The conditions for recovering the herbicide chloridazon from the soil were studied using acetone as the extractant reagent, and the optimum conditions were a time of 15 min for a single extraction. Results showed that 85.7% of the chloridazon was recovered from soil samples.

A metabolite of the herbicide pyridate (3-phenyl-4-hydroxy-6-chloropyridazine, known as CL9673) has been determined in drinking and groundwater.[140] A recovery study using tap water samples spiked with CL9673 at a concentration of 0.1 μg L^{-1} showed a recovery of 84.8%.

Pyridate and its metabolite have also been determined in green cereals, grain and straw.[20] Samples were macerated with acetone–celite and filtered. The acetone extracts were evaporated. The aqueous residue was transferred to a separating funnel with sodium acetate and dichloromethane. The dichloromethane phase contains the herbicide pyridate, and the sodium acetate phase contains the metabolite. Each phase was then extracted further. In the 0.05–1.0 mg kg^{-1} range, recoveries are

between 73.7 and 109% from green plants, between 77 and 102% from grains and between 77.3 and 87.5% from straw.

5 IDENTIFICATION AND DETERMINATION

The wide range of physicochemical properties covered by these compounds explains why many analytical techniques have been used to determine them. Table 5 summarizes the techniques employed for the compounds' determination. As can be observed in the table, HPLC is the procedure most employed to separate and detect miscellaneous pesticides. This may be attributed to general guidelines that have been established to generate new pesticides, less hazardous for human beings. Pesticides are being made more water soluble, more polar and less volatile. This group of characteristics makes HPLC an ideal technique for determining them.

5.1 Gas Chromatography

Direct determination of imidacloprid by GC is not possible because of its thermolabile and polar *N*-nitroguanidyl moiety. However, a method for determining imidacloprid in water and soil samples, after hydrolysis in a basic medium, followed by chromatography–MS and selected ion monitoring (SIM) has been reported.[53]

In contrast, acetamiprid is directly determined by GC with electron-capture detection (ECD).[54] The operating conditions of GC include the use of a packed column. The inlet and detector temperatures were both 320 °C, and the column temperature was 260 °C. In the same context a method for determining acetamiprid and its metabolites was developed by GC/ECD. Acetamiprid and its metabolites in crops were derivatized to methyl 6-chloronicotinate through alkali hydrolysis, potassium permanganate oxidation and then esterification with diazomethane.[55]

Bipyridylium herbicides cannot be determined by GC unless they are converted into volatile compounds. Reduction of DQ and PQ with $NaBH_4$ in the presence of a catalyzer such as $NiCl_2$ makes it possible to obtain the hydrogenated derivatives that could be detected by a NPD (nitrogen phosphorus detector).[79,84]

CQ is also determined by GC.[82] The technique is based on an in vitro multistep reaction by which CQ is initially N-demethylated with a potassium pentafluorothiophenolate followed by a further reaction with an excess of reagent to produce the pentafluorothiophenyl derivative. ECD and MS were used for quantitative determination and identification. However, Mortimer and Weber[192] reported that the method contains a significant error and it is not specific for CQ.

Determination of dinitroaniline herbicide concentrations in soil, air and plants has usually been carried out by GC with ECD,[98,101] NPD[99,153–155] or MS.[98,99,153,155] The concentrations of these herbicides were determined by both NPD and ECD and confirmed by their mass spectra. In this way, benefin, butralin, dinitramine, ethalfluralin, isopropalin, pendimethalin and trifluralin have been determined, often together with herbicides of other types in several matrices. Figure 1 shows the GC/MS chromatogram at the detection limit of $0.01\,\mu g\,g^{-1}$ of pendimethalin and three other herbicides in soil samples.

However, oryzalin requires a general derivatization method, since the intact chemical does not possess good gas chromatographic properties. The di-*N*-methyl derivative has been well recognized and conversion of oryzalin to this derivative has been used in determination and characterization by GC/MS.[157]

Analysis of chloroacetamides has also usually been carried out by GC with different detectors.[26,103,105–108,110–114,116,117,119,120,158–161,163,164,183,184,189] With nonspecific detection such as FID (flame ionization detection) the sensitivity of the determination is relatively low and laborious purification of the samples is needed.[159,183,184,189] To avoid these drawbacks, a comprehensive two-dimensional gas chromatograph with FID was constructed and evaluated for fast separation and analysis of different pesticides, among them alachlor, metalachlor and trifluralin.[160]

GC/NPD has been applied to the analysis of alachlor, propalachlor, butalachlor, metolachlor and two alachlor degradation product residues.[26,106,116,120,158] ECD is a highly sensitive detector for these compounds. It has been used in the analysis of acetochlor, alachlor, butachlor, metolachlor and propachlor.[110,113,154,161] Other authors have used ECD to analyze alachlor and its metabolite after derivatization to the heptafluorobutyryl derivative.[119] This method is highly sensitive but the analysis is complicated. The detection of chloroacetamides also has been performed using ECD and NPD in parallel.[105]

GC/MS has been used as a confirmatory technique.[26,108,110,116,120] GC/MS also allows routine determination of chloroacetamides simultaneously with other herbicides such as triazines, carbamates and phenoxyacetic acids.[103,107,112,114,117,163] Isotope dilution GC/MS has been used to determine alachlor, metolachlor, atrazine and simazine in water and soil.[111] Known amounts of ^{15}N, ^{14}C-alachlor and $^{2}H_5$-atrazine are added to each sample as internal standards. The GC/MS system with data acquisition in SIM mode was used to quantify herbicides in the extract.

The chromatographic separation of enantiomers and diastereoisomers of some acetamide pesticides was investigated using achiral and chiral GC/MS.[164] The

Figure 1 GC/MS detection limit of simazine (Sim), thiazopyr (Th), pendimethalin (Pen) and hexazinone (Hex) in soil samples in SIM ($0.01\,\mu g\,g^{-1}$). (Reproduced with permission from R.A. Pérez, C. Sánchez-Brunete, E. Miguel, J.L. Tadeo, *J. Agric. Food Chem.*, **46**, 1864–1869. Copyright (1998) American Chemical Society.[153])

compounds studied were alachlor, acetochlor, metalaxyl, metolachlor, and dimethenamid. Whereas alachlor is achiral, all the other compounds are axial- and/or C-chiral and consist of two or four stereoisomers, as is shown in Figure 2.

Alloxydim-sodium herbicide and its degradation product have been determined by GC/MS. Residues were derivatized and transformed into 2-methoxycarbonyl-3,3-dimethylpentane-1,5-dioic acid, which was then determined.[124]

A GC method with NPD is described for the determination of amitrole in water, plant and soil samples. The method is based on the acetylation of amitrole with acetic anhydride.[130,133]

Pyridine-based molecules have seldom been determined by GC. Thiazopyr has been the one most often determined by GC and different detectors, such as

Figure 2 EI (electron impact) mass and SIM chromatograms (m/z 223 + 230, (a), (b); m/z 206 + 237 + 238, (c), (d)) showing elution of acetamide pesticides on: (a), (c) the achiral SILOV (silar 10c/ov1701) and (b), (d) the chiral OV1701-BSCD (*ter*-butyldimethylsilyl-β-cyclodextrin) HRGC (high-resolution gas chromatography) columns. Note the elution of single peaks from the achiral column. Note the marginal resolution of acetochlor into the atropisomers on the chiral column. Note the resolution of metalaxyl, metolachlor and dimethenamid into two or three isomers on the chiral HRGC column. Abbreviations: AL, alachlor; AC, acetochlor; MX, metalaxyl; ME metolachlor; DM, dimethenamid. Retention times in minutes. (Reproduced with permission from H.R. Buser, M.D. Müller, *Environ. Sci. Technol.*, **29**, 2023–2030. Copyright (1995) American Chemical Society.[164])

ECD,[134] NPD and MS[135,153] have been used. The derivatization of fluridone with phosphorus tribromide to determine it by GC/ECD has been proposed as an alternative or confirmatory procedure.[137]

5.2 High-performance Liquid Chromatography

Several liquid chromatographic methods have been reported for determining macrocyclic lactone residues in various matrices. HPLC-fluorescence detection after dehydration of the residues with trifluoroacetic anhydride[10,37–43,45,46,49] is the most widely applied determination technique. The major advantages of this method are instantaneous fluorescence derivatization, high sensitivity, improved selectivity and the ability to quantify ivermectin, avermectin B_1, emamectin and their 8,9-δ degradation product. Figure 3 shows a typical chromatogram for the derivatized avermectin B_1 containing a B_{1a} : B_{1b} ratio of about 93 : 7 in untreated whole apples fortified with avermectin B_1 at the 2.1 ppb level.

A more rapid HPLC method has been described[44] for the detection of abamectin in cucumber and lettuce. The method employs UV detection based on the conjugated-diene chromophore of abamectin, which has an absorbance maximum at 245 nm. This method, however, lacks sensitivity and the δ 8,9-isomer is not measured. In addition, when the method is employed with other samples, it shows matrix peaks that interfere with it and prevent quantification of abamectin. Junsuo and Qian[48] use immunoaffinity chromatography for cleanup and concentration followed by UV detection.

Several methods have been described for the determination of abamectin and emamectin benzoate using radiolabeled compounds (^3H and ^{14}C) in a variety of samples.[9,21,47,141] The samples were analyzed by HPLC and the compounds determined on a direct liquid scintillation counter (LSC).

The chloronicotinyl insecticide imidacloprid has been extensively determined by reversed-phase high-performance liquid chromatography (RPHPLC) with UV detection at 270 nm using a mobile phase of acetonitrile–water.[4,50,51] The limits of detection ranged from 0.01 to 1.0 mg kg^{-1} depending on the material analyzed. The methodology for determining imidacloprid residues in vegetables[52,193] by HPLC diode array detection (DAD) has been developed owing to its suitability for selecting the optimum wavelength for maximum sensitivity and confirmation from UV spectral information.

HPLC with pulse amperometric detection (PAD) has been used to determine the insecticide imidacloprid and its major metabolite 6-chloronicotinic acid in soil. Electrochemical study of the compounds demonstrates the reduction and adsorption processes on the mercury electrodes. PAD overcomes electrode fouling problems by repeated and continuously applying cleaning potentials to the working electrode. The measurement potential was −1300 mV.[11] Figure 4 gives the chromatograms obtained with amperometric detection in direct current (DC) mode and pulse mode.

Figure 3 Typical LC chromatograms for apple fortified with 2 ppb avermectin B_1 (B1a) (a) and apple control, 0 ppb avermectin B_1 (b). (Reproduced with permission from J.A. Cobin, N.A. Johnson, *J. AOAC Int.*, **78**(2), 419–423 Figure 3. Copyright (1995) AOAC International.[41])

Azadirachtin is nonvolatile and highly polar. It is unsuitable therefore for GC and only has UV absorption at a very short wavelength. RPHPLC has been successfully used for separation and quantification of azadirachtin.[13,22,56–58] The problem is that common aliphatic and aromatic solvents and surfactants used to formulate the products interfere in the region of the azadirachtrin-A peak.[57]

HPLC is the analytical instrument of choice for ammonium quaternary salts because they are readily soluble in water and in another polar solvent and are not volatile. The most commonly used stationary phases are reversed-phases (RP), comprising silica bonded to carbonate chains of several lengths, mainly C_8 and C_{18}. Ion-pair formation in LC (liquid chromatography) with a UV detector is a common technique for determining quaternary ammonium compounds, for example by using hexanesulfonate,[70] heptanesulfonate,[60,95] octanesulfonate,[17,83,89,94] ammonium formate,[152] ammonium acetate[67,145] or potassium bromide.[96] as counter ions.

C_{18}- and C_8-bonded silica stationary phases always have free silanol groups that complicate the analysis of quaternary amines like bipyridylium herbicides, provoking the

Figure 4 Chromatograms in (a) DC detection mode, E = −1300 mV, (b) pulse mode. Flow rate: 1.0 mL min^{-1}, injection volume: 25 μL, drop size 2.5 mm^2, amount injected: (A) 500 ng and (B) 100 ng of each substance. (Reproduced from N. Ruíz de Erenchum, Z. Gómez de Balugera, M.A. Goicolea, R.J. Barrio, *Anal. Chim. Acta*, **349**, 199–206. Copyright (1997) with permission of Elsevier Science B.V.[11])

appearance of tailing peaks and increasing their width, and originating a variation in the retention times even when the same column is used. To avoid this one of four actions can be taken:

1. Choose another type of column.
2. Reduce the ionization of the silanol groups by employing mobile phases of pH < 4.
3. Add a silanol group blocking agent to the mobile phase.
4. Increment the ionic strength of the mobile phase.

In addition to the counter ion, the mobile phases reported contain an acid, such as phosphoric acid,[15,17,61,62,70,81,89,94–96,152,194] glacial acetic acid[67] or trifluoroacetic acid,[145] together with a silanol group blocking agent, such as diethylamine[17,70,89,94,194] or triethylamine.[95,96] Because of the basic character of the latter, they also help to maintain the pH around 3.

In order to avoid the free silanol group effect, analytical columns are being substituted for the base made from silica particles for polymeric packings such as polystyrene–divinylbenzene. These columns are also more resistant to the acid pHs.[16,68] The mobile phases contain phosphoric acid and triethylamine.

The utility of silica as a stationary phase for HPLC analysis of quaternary ammonium compounds has been discussed.[63,64,76,77] A silica column with sodium chloride as an ion-pair reagent in acetonitrile–water as the mobile phase provided rapid efficient selective separation of PQ and DQ.[76,77] The mechanism involved in this chromatographic process has not been well defined and the interactions between the normal phase (NP) and the herbicides may include ionic interactions between the positive charge of the ammonium quaternary group and the negative one of the silanol group. The herbicide fixed to the silica can be liberated using displacing agents in the mobile phase such as tetramethyl ammonium

hydroxide.[63,64] Using silica columns, PQ, DQ and DF were chromatographed as symmetrical well-resolved peaks whose retention time can be controlled by the concentration of added salts.

An analytical column of GCB has also been tested for chromatographic determination of DQ, PQ and DF.[66] The elution was performed with a gradient of pH 3 aqueous solution of tetramethylammonium hydroxide and ammonium sulfate, and methanol. A hypercarb column was found to give a low probability of false positives for bipyridylium herbicides because it is selective for polar compounds.

Conventional detection of ammonium quaternary compounds in HPLC is usually achieved with UV and DAD detectors. The most commonly used is the UV detector, monitoring wavelengths of 310 nm for DQ, 255 nm for PQ and 258 nm for DF.[17,60,63,64,66,70,81,83,89,94–96] In combination with DAD, an unambiguous identification in environmental samples is sometimes possible.[16,67,68,76,77]

However, the international agencies prefer methodologies which confirm identity using MS. The direct flow injection thermospray (TSP) MS of DQ and PQ demonstrates that the addition of a volatile buffer salt to the mobile phase is necessary because it provides a strong increase in sensitivity.[61,144]

The problem of coupling HPLC with MS detection to determine ammonium quaternary compounds is that nonvolatile ion-pairing reagents are used to facilitate chromatography. These reagents contain insoluble sodium and potassium salts, phosphate and sulfonates, which are not amenable to MS confirmation of ammonium quaternary compounds, because these salts quickly precipitate and clog the HPLC/MS interface.

Yoshida et al.[145] and Barcelo et al.[15] characterize PQ, DF, DQ, MQ and CQ by HPLC/TSP/MS. Under RP conditions and using ammonium formate or ammonium acetate as ionizing additives, 1–2 μg of each compound was positively identified under full scan conditions. For the characterization of DF, a postcolumn ion-pairing extraction system was used. An aqueous mobile phase with sulfonate-type counter ion was applied and an extraction solvent containing cyclohexane–dichloromethane–*n*-butanol was used in HPLC/TSP/MS.[152] An HPLC method compatible with particle beam (PB) MS for DQ and PQ confirmation has also been developed; it ensures correct identification and quantification of both compounds.[67]

An analytical method for the determination of MQ residues has also been reported.[80] The final separation and determination is based on ion-pair chromatography using a column switching system and CD.

An HPLC chromatographic method for the simultaneous determination of the dinitroaniline herbicides dinitramine, ethalfluralin, trifluralin, pendimethalin and isopropalin has been proposed. In order to achieve the separation of dinitroaniline herbicides, different RP (C_1,C_6,C_8, (octadecylsilica) ODS-1 and ODS-2) columns were employed.[18] Each column allowed separation of the five herbicides with different water–acetonitrile mixtures. The elution order was the same (first and last, respectively) for dinitramine and isopropalin on all the columns tested, whereas ethalfluralin, trifluralin and pendimethalin were eluted with different orders in the different columns.

Analytical procedures have also been described for the trace analysis of oryzalin and prosulfalin residues in soil using an optimized HPLC system.[100] The method requires no derivatization.

HPLC has recently been shown to be useful for trace analysis of a number of pesticide residues. Pendimethalin, chlorpyriphos, and the two esters 2,4-DIOE (isooctyl ester of (2,4-dichlorophenoxy)acetic acid) and 2,4-DPBEE (butoxyethanol ester of 2-(2,4-dichlorophenoxy)propionic acid) were quantified by HPLC using a C_{18} column, a methanol–water (82 : 18) mobile phase and UV detection.[156]

HPLC methods allow direct determination of chloroacetamides and their metabolites by UV and/or ED (electrochemical detection).[115,118,165,183,185] As a complementary technique, HPLC/DAD can be employed for confirmation of these herbicides only if there is sufficient quantitative enrichment.[102,116,165]

HPLC/MS/MS has been used to detect and identify alachlor, its ethanesulfonate metabolite, and its hydrolysis product 2,6-diethylaniline in water and urine.[104,167] One relatively new method for analyzing herbicides in water involves using HPLC coupled with MS by means of electrospray ionization (ESP). The technique has been applied to the trace analysis of oxanilic and sulfonic acids of acetochlor, alachlor and metolachlor.[109]

Chiral HPLC using modified cellulose and phenylglycine columns also showed some isomer resolution and was used for the isolation of acetochlor and metolachlor. The (+) and (−) enantiomers were assigned to acetochlor and metalaxyl using chiral HPLC in combination with chiroptical detection.[164]

Clethodim herbicide has been separated from acid and photodegradation products (PDPs) by HPLC.[5] Using an adequate mobile phase gradient, 31 peaks were separated following photocatalysis, as illustrated in Figure 5. Addition of acetic acid to the mobile phase improved peak symmetry and HPLC separation. Sethoxydim and its major active metabolite, sethoxydim sulfoxide, has been determined by normal-phase high-performance liquid chromatography (NPHPLC) using a silica column and methanol–dichloromethane containing acetic acid.[125]

Figure 5 Chromatogram of PDPs of clethodim showing separation by LC with UV detection at 254 nm. (Reproduced with permission from L.N. Falb, D.C. Bridges, A.L. Smith, *J. Assoc. Off. Anal. Chem. Int.*, **74**(6) 999–1002, Figure 2. Copyright (1991), AOAC International.[5])

The excellent water solubility and the high polarity of amitrole makes it impossible to determine by RPHPLC with the usual aqueous eluent. The retention behavior shows no separation between amitrole and the solvent peaks. It is well known that satisfactory HPLC separations can be achieved in presence of ion-pairing reagents like sodium dodecyl sulfate (SDS),[128,129,131,132] sodium butanesulfate[126] and tetrabutylammonium sulfate.[27] Figure 6(a) is a chromatogram corresponding to an injection of a solution containing $50\,\mu g\,L^{-1}$ of aminotriazole, and Figure 6(b) of a solution containing $0.5\,mg\,L^{-1}$, where the separation between solvent peak and amitrole is accomplished with SDS. The separation has also been done by NPHPLC on a polar cianopropyl-column using hexane, propanol, water with $LiClO_4$ and trichloroacetic acid as electrolytes[19] or using ion exchange chromatography.[126]

The direct UV detection of amitrole suffers from a fairly low absorption coefficient and cannot be used.[126] For greater sensitivity, derivatives of amitrole have to be formed by diazotization by coupling with 1-naphthol-3,6-disulfonic acid.[27,126] Without a prior derivatization step, amitrole is directly detectable by an amperometric technique following ion-pair HPLC separation[19,128,129,132] and coulometric electrode array detection (EAD).[131] HPLC with UV after derivatization and ED required enrichment steps for the determination of concentrations in the range of $0.1\,\mu g\,L^{-1}$. Samples with concentration up to $1\,\mu g\,L^{-1}$ can be directly injected. Using EAD, tap and well water with concentrations down to $0.1\,\mu g$ amitrole L^{-1} can be determined without any enrichment steps.

Thiazopyr was determined by HPLC/DAD in water.[134] It was hoped that DAD would provide spectral information to augment confirmation of incurred thiazopyr and its metabolite residues. Unfortunately, there

Figure 6 Detection limit and system peaks for aminotriazole. Column: C_{18} silica, 5 µm, 15 cm × 0.46 cm internal diameter; mobile phase: 65% acetonitrile 0.05 M SDS at pH 3 with perchloric acid and 35% acetonitrile; ED 0.85 V (vs Ag/AgCl). (a) Injection of 100 µL of $0.05\,mg\,L^{-1}$ solution, 1 µA full scale and (b) injection of 100 µL of a $0.5\,mg\,L^{-1}$ solution, 5 µA full scale. (Reproduced from V. Pichon, M.C. Hennion, *Anal. Chim. Acta.*, **284**, 317–326. Copyright (1993) with permission of Elsevier Science B.V.[128])

were no distinctive wavelength maxima that could be exploited for monitoring purposes.

Several methods for determining of underivatized fluridone in milk, animal tissues and crops by HPLC have been described.[136–138] HPLC methods are advantageous in that they are rapid and avoid the use of hazardous derivative reagents.

Norflurazon and its initial soil metabolite can be determined using HPLC with fluorescence detection.[139] The fluorescence properties of norflurazon dissolved in acetonitrile were examined previously. Adding water or acidifying the solution had no effect on the observed fluorescence. A method for measuring chloridazon with an HPLC microbore column and DAD has been reported.[190]

The application of a simple RPHPLC/UV method for the determination of the contact herbicide pyridate and its main metabolite CL9673 has been described.[20]

Amperometric detection has also been reported for the metabolite.[140]

5.3 Immunoassay

Immunoassay offers certain advantages over conventional instrumental methods for the analysis of pesticide residues. Inmunoassays are highly efficient and cost effective and are ideally suited for screening large numbers of samples for low levels of specific analytes.[195] An enzyme immunoassay uses either a labeled antibody or a labeled analog of the target compound as the detection marker and can be performed in different formats. The most common format is the competive enzyme-linked immunosorbent assay (ELISA). In competitive ELISA, the antibodies specific to the analyte are immobilized onto a solid phase. The enzyme–hapten conjugate and the analyte are added to the antibody-coated tube or plate for incubation. After incubation, the unreacted material is removed, and a substrate and chromogen are added and allowed to react for a short period of time during which the enzyme converts the substrate-chromogen to a colored product. The absorbance can either be measured with a spectrophotometer or estimated visually.

In some ELISAs the solid phases employed are polystyrene wells, balls or tubes, on which the antibody or hapten–protein conjugate are passively adsorbed. The desorption or leaching off of antibody or other proteins which have been passively adsorbed is a major factor that adversely affects sensitivity and precision assays. Variability of wells within microtiter plates has been shown to be the greatest contributor to total assay imprecision. A particle-based ELISA eliminates these imprecision problems through covalent coupling of antibody to the solid phase. The uniform dispersion of particles through the reaction mixture allows for rapid reaction kinetics and precise addition of antibodies.[169,170]

A competitive ELISA for the quantification of free PQ cation was developed using polyclonal rabbit antiparaquat antibodies bound to a magnetic particle solid phase.[74] The immunoassay described utilizes a competitive format. Since enzyme-labeled PQ competes with the unlabeled (sample) PQ cation for the antibody sites, the color developed is inversely proportional to the concentration of PQ cation on the sample. The speed and sensitivity of the method makes it suitable for large numbers of samples in short periods of time.

A carboxylic derivative of metolachlor, *N*-(chloroacetyl)-*N*-(1-methyl-2-methoxyethyl)-2-methyl-4-(4′-carboxybutoxy)-6-ethylaniline, was synthesized and covalently linked to a carrier protein to prepare monoclonal antibodies. An antibody with high binding affinity for metolachlor was used to develop two competitive ELISA procedures, a direct one with enzyme-labeled antigen and an indirect one with an enzyme-labeled second antibody.[186] No cross-reactivity was observed with alachlor, furalaxyl, metalaxyl, and most of the metabolites of metolachlor and metalaxyl.

Antibodies against alachlor were generated using an alachlor–protein conjugate. Alachlor was conjugated to the protein carrier through the chlorine-bearing carbon via a thioether bond. This type of linkage was easily obtained because of the reactivity of the chlorine-bearing carbon with nucleophiles such as glutathione. Furthermore, the sulfur atom facilitates the formation of antibodies that recognize alachlor. Conjugation of alachlor to proteins via the thioether linkage is a simple one-step reaction requiring no synthesis of novel haptens.[123,172] Rabbit polyclonal antibodies generated using the thioether conjugate were useful in the development of a sensitive alachlor ELISA. The ELISA discriminated alachlor from other chloroacetanilide herbicides, although strong cross-reactivity was detected with some thioether metabolites.[171,175] Subsequently an analog of alachlor was conjugated to proteins through a carboxyl group in the methoxymethyl side chain. Antibodies from the carboxy–alachlor conjugate showed even greater specificity towards alachlor and discriminated against other chloroacetamides as well as alachlor thioether metabolites.

Using the same thioether conjugation method, ELISAs for other chloroacetanilines herbicides, metolachlor, amidochlor and butachlor, have been developed.[182] These chloroacetanilide herbicides were easily conjugated to proteins via a thioether linkage.

The ELISA method was evaluated for the detection of alachlor in environmental water samples and was compared with an established GC/MS method. The results indicate that the alachlor ELISA can be effectively utilized as a primary screen to select environmental samples for confirmatory instrumental verification of the presence of alachlor at low parts per billion levels.[168,195] However, an ELISA for the detection of alachlor or putative alachlor metabolites in human urine has been described and compared with HPLC analysis, and the two analytical methods gave results with statistically significant differences.[143]

An automated flow-injection liposome immunoanalysis system was developed using alachlor as a model compound.[176–178] The experimental system consists of an autosampler attached to an immunoreactor column containing antialachlor antibody covalently coupled to glass beads.

The utility of immunoassay techniques as part as groundwater monitoring/compliance programs has been evaluated.[166] There are several commercially available kits for determining chloroacetamides.[121,122,174] The

results provide evidence that immunoassay techniques are simple and suitable. However, false positives should be tested for possible metabolites that may cross-react with the antibody.[173,187]

5.4 Other Techniques

5.4.1 Spectrometric and Spectrofluorimetric Methods

Methods for the determination of PQ and DQ by spectrophotometry have been reported. The spectrophotometric methods most often used are based on their reduction in alkaline solution. Reduction of PQ with sodium dithionite forms a blue reaction product[73,90,92] and reduction of DQ forms a green[71] or red one.[88] Ascorbic acid[65,72] or sodium borohydride[93] also form a blue free radical ion with an absorbance maxima at 600 nm with PQ. PQ and DQ can be determined simultaneously using second-derivate spectroscopy after reduction with NaOH dithionite solution.[85,87]

It should be noted that the reaction product formed with DQ and dithionite is also fluorescent and can be measured using an excitation wavelength of 428 nm and an emission wavelength of 497 nm.[71] Determination of DQ by photokinetic methods has been described;[59,78] it is based on the rate of photoreduction of DQ by ethylenediaminetetraacetic acid (EDTA) sensitized by acridine yellow in absence of oxygen[78] or on the formation of a charge-transfer complex between DQ and cysteine.[59]

5.4.2 Thin-layer Chromatography

The relationships between the structure of N_1- or N_4- substituted 1,2,4-triazoles and their behavior in thin-layer chromatography (TLC) on silica gel were studied. Linear correlations were obtained between the retention parameter, R_m, and the logarithm of the molar fraction of a strong solvent in eight binary solvent systems for five pairs of positional isomers.[6] Detection using 2-dichloromethylbenzoimidazole as the reagent on TLC has been described.[132] A study on the adsorption and dissociation of the herbicide amitrole has been performed using radiolabeled compounds and TLC.[127]

5.4.3 Supercritical Fluid Chromatography

SFC is a suitable technique for determining azadirachtin in crude extracts of neem. Almost all the accompanying substances are less polar than azadirachtin and are eluted quickly. On the RPHPLC they elute very slowly and must be removed by pretreatment. The UV absorbing peak for azadirachtin can be separated from the other substances present in a relatively short time.[12,56] Figure 7 shows the chromatograms obtained by SFC and HPLC. The chief differences between SFC and HPLC were the much longer time required for an HPLC separation and the much larger volume of solvent required.

Figure 7 Chromatograms of triterpenoids found in neem seeds. (a) SFC and (b) HPLC. Peak identification: (1) nimbin, (2) salamin, (3) 6-desacetylnimbin, (4) 3-desacetylsalamin, (5) 3-tigloylazarachtol, (6) azadirachtin, (7) azadirachtin-D, (8) 3-acetyl-1-tigloylazadirachtinin, (9) azadirachtin H, (10) salannolide, (11) azadirachtin I. The structure of the compound SL_2 has not been determined. The peak areas do not represent their natural abundance in seeds, as the minor components have been enriched to make them more easily visible. (Reproduced from S. Johnson, D. Morgan, *J. Chromatogr. A.*, **761**, 53–63. Copyright (1997) with permission of Elsevier Science B.V.[58])

5.4.4 Capillary Electrophoresis

CE techniques have proven to be promising alternatives to the separation and/or analysis of various ionogenic pesticides. Separations in CE are based on differences in the electrophoretic mobility of the injected ions. Tomita et al.[91] have described the use of CE to determine PQ and DQ. The optimal conditions for CE separation of DQ, PQ and DF are well established[14,69,75,147] and have been compared with HPLC determination.[60] CE was simpler and cheaper, but HPLC offered a higher sensitivity for real samples and was independent of the matrix effects. Investigation into the application of indirect UV detection in CE published by Galceran et al.[146] showed the suitability of an absorbing carrier electrolyte for the determination of the nonabsorbing quats, CQ and MQ, and also the simultaneous detection of the

Figure 8 Electroferograms obtained under optimal conditions, 10 mM PP (pH 2.5) 10% MeOH. Applied potential, +20 kV; hydrodynamic injection, 5 s, at different detection wavelengths. Standard solution: PQ, 19.6 μg mL^{-1}; DQ, 37.3 μg mL^{-1}; EQ (ethyl viologen), 38.0 μg mL^{-1}; CQ, 25.2 μg mL^{-1}, MQ, 25.5 μg mL^{-1}, DF 27.6 μg mL^{-1}. * Negative peak (the arrows indicate a data acquisition interval time during which a negative peak is reversed and plotted as a positive peak). (Reproduced from M.T. Galceran, M.C. Carneiro, M. Díez, L. Puignou, *J. Chromatogr. A.*, **782**, 289–295. Copyright (1997) with permission of Elsevier Science B.V.[146])

absorbing quats. Figure 8 shows the electropherograms obtained at the optimal conditions, 10 mM PP (1-(4-pyridyl)pyridinium chloride hydrochloride) (pH 2.5) and 10% methanol, at two different wavelengths, 205 nm and 257 nm. CE/MS have also been proposed for the characterization of these herbicides.[148,149]

CE/UV has been used for analysis of alachlor and metolachlor together with atrazine and simazine. The reported method is simple, rapid and efficient and the compounds can be separated in a relatively short time.[179]

5.4.5 Voltammetry

PQ and DQ have been determined by square wave voltammetry (SWV).[150,151] This method is nonselective because the PQ and DQ species were reduced at the same potential values. However, these compounds present similar toxicities and are often used in mixtures, so that cumulative residue analysis is needed.

An electrochemical study of the chloridazon oxidative process in a silica-modified carbon paste electrode in Britton–Robinson buffer (pH = 11.30) using different voltametric techniques has been carried out.[191] An oxidation wave is obtained at 900 mV and the system is irreversible and controlled mainly by adsorption. No interference of other herbicides has been observed and good results were obtained when this method was applied to the determination of chloridazon is soils.

5.4.6 Other Characterization Methods

The chloroacetanilide herbicides acetochlor, alachlor, butachlor, propachlor and metolachlor and their sulfonic acid metabolites were studied by nuclear magnetic resonance (NMR) spectroscopy and fast atom bombardment mass spectrometry (FABMS).[181,188] Although similar in structure, the sulfonic acid metabolites were successfully characterized.

Fiber optic evanescent wave spectroscopy (FEWS) is a technique which allows in situ mid-infrared (MIR) absorption spectroscopy to be carried out in aqueous environments. The potential of this technique for monitoring alachlor at parts per million levels demonstrated that it can be employed as an alarm level indicator.

6 FOOD AND ENVIRONMENTAL APPLICATIONS

6.1 Macrocyclic Lactones

Zeng et al.[7] studied cytochrome P-450 isoforms responsible for the metabolism of abamectin and ivermectin in the rat. The conclusions presented are based on results from incubation with liver microsomes from induced rats. The enzymatic activity of the cytochrome P-450 had been induced to increase the metabolism of the abamectine because of the limited quantities of metabolites produced by liver microsomes from untreated rats. The study was performed using radiolabeled compounds and metabolite profiles were determined by RPHPLC. One-minute fractions of the column eluate were collected into miniscintillation vials and mixed with a scintillation cocktail. The radioactivity of these samples was determined by scintillation spectrometry.

Information on residue levels, dissipation rates, and translocation resulting from a field treatment with ^{3}H-avermectine B_1 was applied to orange and lemon fruits and lemon leaves. Whole fruit residues of avermectin at harvest are less than 0.001 ppm.[141] Translocation from

the treatment sites is so low as to be undetectable. Because of short persistence, avermectin should cause minimal environmental and food contamination.

Aerobic and anaerobic incubation of microbially active soil with [^{14}C]emamectin benzoate resulted in measurable evolution of $^{14}CO_2$. Chromatographic and mass spectral analysis of extractable residues demonstrated the degradation of the compounds.[9] The degradation in soils follows biphasic kinetics and is relatively rapid between days 0 and 60, becoming less rapid between days 120 and 360. The results of this study demonstrated that emamectin benzoate is biodegradable in soil, forming multiple residual products, and is eventually incorporated into soil components and mineralized to CO_2. Laboratory studies of the fate of ^{3}H-labeled avermectin B_{1a} in Lufkin fine sandy load, Houston clay and coarse sand demonstrated that under aerobic conditions the compound was degraded at a fairly rapid rate to at least 13 radioactive products.[21]

Emamectin benzoate and its δ isomers were determined in a lettuce and celery field trial.[45] The emamectin benzoate level dissipated rapidly on days 0–1 of the postapplication period and then dissipated thereafter at a slower rate. At seven days post-treatment, emamectin benzoate residues were not detected.

Rapid uptake of ^{3}H-emamectin benzoate by bluegill sunfish was observed. The steady-state bioconcentration factors indicate that emamectin benzoate neither bioconcentrates in individual aquatic organisms nor biomagnifies in the food chain.[47]

6.2 Chloronicotinyls

Determination of imidacloprid in water, after hydrolysis in basic medium, followed by GC/MS in SIM mode has been applied to groundwater samples from Santa Maria farm, near Granada (Spain) and in tap water from the city of Granada itself. Imidacloprid was not found above of detection limit ($0.16\,\mu g\,L^{-1}$).[53]

Imidacloprid residues have been extracted from vegetables and determination was performed by HPLC/DAD. Fifty-four vegetable samples (peppers, tomatoes and cucumbers) with incurred residues from three different greenhouse plantations, treated with Confidor™ 20 LS (Bayer; 20% (w/v) of imidacloprid) at different doses and collected during the week after treatment, were selected to evaluate the effectiveness of the proposed method. Residues of imidacloprid were found in all samples in the $0.01-0.3\,mg\,kg^{-1}$ range.[52]

The behavior of insecticide imidacloprid in rice and cucumbers was determined by HPLC/UV. The method was applied to determine the residues and rate of disappearance of imidacloprid from rice (nursery box treatment, 1 g of active ingredient/1800 cm^2) and cucumber plants (stem injection, 20 μg of active ingredient per plant). The insecticide incorporated into the plants decreased rapidly with a half-life of less than 3 days. In the rice, however, it controlled the brown planthopper even 60 days after application, with the marginal concentration of $0.01\,mg\,kg^{-1}$.[4]

6.3 Tetranortriterpenoids

The neem tree, originally from India and Pakistan, has received much attention, thanks to the many valuable insecticide properties of azadirachtin. The compound is not easily separable from the many compounds of similar structure and polarity, of which over 100 have been isolated. The quantitative determination of the natural insecticide azadirachtin in crude extracts of neem seeds can be carried out by packed column SFC, with detection by UV absorption at 210–220 nm using CO_2–methanol as the mobile phase.[12] Almost all the accompanying substances are less polar than azadirachtin and elute quickly.

The HPLC procedures for the quantitative determination of azadirachtin in an insecticidal formulation utilize detection with UV absorption at 215 nm. Formulations from neem kernels may contain additional constituents such as triglycerides, fatty acids and surfactants which can interfere with chromatographic analysis. Separation of the interferences is a prerequisite for analysis.[22,57,58]

The hydrolysis of azadirachtin was studied in several natural waters. Azadirachtin appeared to be more susceptible to hydrolysis than synthetic organophosphates. Accordingly, azadirachtin is expected to be nonpersistent in water.[13]

The stability of azadirachtin was examined in six common organic solvents (chloroform, acetone, ethyl acetate, acetonitrile, methanol and ethanol) to help in the development of formulations.[56]

6.4 Ammonium Quaternary Salts

Both CE and ion-pair RPHPLC have been used for the determination of PQ, DQ and DF. Ion pair RPHPLC offers greater sensitivity for determination of herbicides in crop waters. The results obtained show that three samples contained PQ.[60]

Analysis of DQ, PQ and DF in water has been performed using SPE on silica cartridges followed by NPHPLC determination. To show the applicability of the method in routine analysis of natural waters, three samples were taken from three different places in the Valencian Community (Spain): from irrigation channels of Ribarroja del Turia, El Palmar and Puçol with chemical oxygen demand (COD) values of 1.4, 3.9 and 12.0 mg $O_2\,L^{-1}$, respectively. DQ was found in the El Palmar and Ribarroja del Turia samples at concentrations of

6 and 13 $\mu g\,L^{-1}$, respectively.[63] An automatic sample preparation device (OSP (on-line sample preparatory), Merck) was employed to determine these pesticides. The procedure was applied to monitor the three herbicides in drinking and surface water. DQ, PQ and DF were not detected in drinking water. Twelve surface water samples from the natural park of L'Albufera (València, Spain) were analyzed. The pesticide presence was detected in four samples at concentrations ranging from 0.4 to 0.8 $\mu g\,L^{-1}$.[64]

An on-line SPE coupled with an HPLC procedure has been developed to determine DQ, PQ and DF in water, using GCB for extraction and determination.[66] Four surface waters from Torreblanca Natural Park (Castelló, Spain) were analyzed. Pesticides were found in three of the four samples at levels between 0.1–0.25 $\mu g\,L^{-1}$ after passing 50 mL of water into the extraction cartridges.

Various techniques are used to improve contact of aquatic herbicides with submerged weeds to facilitate control. One commonly used method is to add one of a group of adjuvants, known as polymers to the spray tank mixture. Information on how these adjuvants affect herbicide distribution will be helpful for predicting movement of DQ from treated areas. DQ was applied in a lake to three 1.6 ha plots either with a polymer, which reportedly aids in sinking and confinement of aquatic herbicides, or without a polymer.[62] DQ was analyzed by extraction with C_8 and ion-pair RPHPLC. Forty-six percent of the samples collected at the edges of the plot did not contain detectable DQ residues and only 66% of the sample with detectable DQ contained more than the drinking water tolerance (10 ppb).

A method for measuring CQ based on an in vitro multistep reaction by which CQ is initially N-demethylated and then derivatized was proposed.[82] ECD and MS were used to analyze cotton seed harvested from cotton plants treated with various concentrations of CQ. Concentrations between 0.01 and 1.0 $\mu g\,g^{-1}$ were determined with a limit of detection of 0.003 $\mu g\,g^{-1}$.

The herbicides DQ and PQ can be analyzed in edible oils by HPLC/UV at 210 nm using an ODS column. Recoveries from 90 to 93% can be obtained with a pH 7 aqueous phosphate buffer extraction procedure and cleanup with C_{18} cartridges. Only two of the 12 analyzed virgin oil samples from olive crops sprayed with these herbicides contained DQ residues.[81]

A photokinetic method based on photoreduction with EDTA and acridine yellow using polarography has been applied to DQ in potatoes. The concentration of DQ found in the potatoes ranged from 13.74 to 24.51 $\mu g\,g^{-1}$.[78]

A spectrophotometric method for the determination of PQ using a reducing agent was described[93] using sodium borohydride and alkaline medium to give a blue radical ion with an absorbance maximum at 600 nm. The method was applied to the determination of PQ in human samples, such as blood, urine and mother's milk compared to food and environmental samples.

6.5 Dinitroanilines

Studies were undertaken to evaluate the dissipation of pendimethalin in two Canadian field soils following application of an emulsifiable concentrate formulation in the spring. Residues of pendimethalin were determined by extraction with acetonitrile and GC/ECD. Over a longer period there was no leaching of the herbicide below 10 cm.[101] Residues of pendimethalin were carried over in soils to the next crop year in amounts between 12 and 28% of that applied (1.11 $kg\,ha^{-1}$).

Pendimethalin, alachlor and metolachlor were often found to be present in rainfall in Indiana and Ohio. Analysis was performed by GC with dual-column using NPD.[154] Concentrations were in the range 0.1–1.0 $\mu g\,L^{-1}$. During periods of frequent or prolonged rainfall, concentrations decreased sharply. Concentrations in the next rainfall generally were higher that those at the end of these periods, consistent with a scavenging effect of precipitation on the local atmospheric load of these compounds.

A method based on the extraction of soil samples in small columns has been used for the determination of pendimethalin and other herbicides in soil. Soil samples from experimental fields taken at different times after treatment from the low layer were analyzed and the values were similar to those obtained using a conventional LLE method.[153] Soil from experimental fields treated with pendimethalin was sampled at various times. A concentration of about 3 $\mu g\,g^{-1}$ was found at the beginning of the application. One month later the concentration decreased to 1.2 $\mu g\,g^{-1}$.

6.6 Acetamides

Determination of the ethanesulfonate metabolite of alachlor was performed by RPHPLC/UV.[104] Eleven water samples (ground and surface) collected from Indiana and Ohio were analyzed. Of these 11 samples, 9 were shown by HPLC to contain ethanesulfonate varying in concentration from 0.6 to 74 $ng\,mL^{-1}$.

SPE was combined with HPLC and electrospray ionization mass spectrometry (ESIMS) for the trace analysis of oxanilic and sulfonic acids of acetochlor, alachlor and metolachlor. The isolation procedure separated the chloroacetanilide metabolites from the parent herbicides during the elution from C_{18} cartridges using ethyl acetate for parent compounds followed by methanol for the anionic metabolites.[109] Concentrations in the nanogram per liter range were found in surface and groundwater

samples. Extraction of butachlor with XAD-2 resin and determination with GC/ECD was described.[113] Pesticide residues in river and surface waters can be identified and determined. Residues of butachlor were frequently detected when it was applied to control the weeds in flooded paddies but the results indicate that the herbicide was not persistent in the aquatic environment.

A method for determining trace levels of butachlor, pretilachlor, and other herbicides in river water has been developed. The method is based on C_{18} SPE, followed by GC/MS/SIM.[103] Recoveries at the 0.5 or 2.5 $\mu g\,L^{-1}$ fortification level were between 79 and 98%. The detection limits were 0.01 $\mu g\,L^{-1}$. The analytical findings on surface water samples collected from rivers indicated that most of the pesticides were detected in river water at 1–10 $\mu g\,L^{-1}$ levels during the first 2–4 weeks after application in the fields. A similar method was reported for determining alachlor, butachlor and other herbicides in a dissolved and suspended phase of river water.[112] This method was applied to monitor herbicides in river water from the Shinano River (Japan). Butachlor was detected in some filtered water samples.

A method for the simultaneous identification of neutral and acidic pesticides in natural water[114] includes enrichment of the compounds by SPE on GCB, followed by sequential elution of the neutral and acidic pesticides and derivatization of the latter fraction with diazomethane. Identification and quantification of the compounds was performed by GC/MS. The method has been used to analyze various natural waters including rainwater, roof runoff, surface water and groundwater. Alachlor was frequently detected in rainwater and runoff water during the application period of pesticides. Concentrations were 16 $ng\,L^{-1}$ and 19 $ng\,L^{-1}$, respectively.

Heyer et al.[105] describe SPE with RP-C_{18} adsorbent for the analysis of alachlor and the development of a micro LLE method following GC/ECD and NPD determination of alachlor and its metabolites DEA (2,6-diethylamine) and CDEA (2-chloro-2′,6′-diethylacetanilide). Both methods were applied to the analysis of more than 200 groundwater samples during a field study and gave similar results. The concentration of alachlor was around 0.5 $ng\,L^{-1}$. Degradation products of alachlor were not found in the field study.

Atrazine, propachlor, butachlor, metolachlor, alachlor and two alachlor products were determined in water, also using a micro LLE.[26] The method involves a one-step extraction of water samples with *n*-hexane followed by direct analysis of extracts using GC/NPD or GC/MS. The analytes detected in the five groundwater samples included alachlor (0.1–1.2 $\mu g\,L^{-1}$) and metolachlor (0.1–2.5 $\mu g\,L^{-1}$). The target alachlor degradation products were not detected in these analyses.

The corn herbicide acetochlor was detected and analyzed by GC/MS. The concentrations and fluxes of acetochlor in rain and in the Blue Earth River in Minnesota were reported. Acetochlor was consistently observed and the concentrations in both rainwater and the river were in the 10–250 $ng\,L^{-1}$ range in most samples.[102]

A combination of HPLC/DAD and GC/NPD with UV and MS confirmation, respectively, has been applied to the determination of trace levels of herbicides in relatively clean water samples by LLE. Illustrative examples of the determination of several herbicides in estuary water samples from the Ebro Delta (Tarragona, Spain) are shown. Alachlor and metolachlor were the most commonly found acetanilides, with concentrations levels varying from 5 $ng\,L^{-1}$ to 5 $\mu g\,L^{-1}$.

Analysis of alachlor was performed by immunoassay using EnviroGard™, and 67 well samples were analyzed. Alachlor was contained in many samples that are positive by immunoassay. In fact, of the 18 positive well samples by immunoassay, just six were found to have alachlor by HPLC.[166]

SPE and ELISA were combined for the trace analysis of the herbicide alachlor and its major soil metabolite ethane sulfonic acid. These compounds were isolated from water by SPE on C_{18} and eluted sequentially with ethyl acetate and methanol. Analyses of surface and groundwater samples were confirmed by GC/MS and HPLC/DAD. Results showed widespread occurrence of ethane sulfonic acid in the midwestern USA, with concentrations ranging from <0.10 to $>10\,\mu g\,L^{-1}$.[171]

The ELISA method was evaluated for the detection of alachlor in environmental water samples and was compared with a GC/MS method. In analyses of environmental water samples ELISA was less accurate and precise than GC/MS.[162]

Unexpectedly high frequencies of positive responses were observed in ELISA screening for alachlor in private rural wells, when samples were analyzed using the EnviroGard™ Alachlor Plate Kit. The majority of the positive responses were false positives with respect to alachlor. In the false positive samples, most appear to be due to the ethanesulfonate metabolite of alachlor. Confirmation testing for alachlor used SPE and analysis by GC/MS. A method using SPE and HPLC/UV was developed for the analysis of the metabolite.[170,175]

An immunoassay for detecting alachlor or putative alachlor metabolites in human urine has been developed and compared with measurements obtained by HPLC analysis of urine hydrolyzate for DEA.[143] Twenty applicators and seven hauler/mixers participated in the study. Also, eight employees of the application companies who were thought to have limited exposure to pesticides submitted urine samples for alachlor dose estimation. The ELISA and HPLC analytical methods gave different

results because the metabolism and excretion of alachlor is not well defined.

Human alachlor exposure has commonly been estimated by quantifying the hydrolysis product DEA, of alachlor metabolites in urine.[167] The alachlor metabolite was identified by using HPLC/MS/MS to analyze extracts of urine samples from subjects who were occupationally exposed to alachlor.

Several herbicides widely used to control weeds in corn (atrazine, alachlor, metolachlor and pendimethalin), have been determined in soil and water.[120] Analysis of herbicides was performed by GC/NPD and GC/MS. Soil samples from corn fields after harvest were taken in several fields located in Spain and water was taken from wells located in the fields. Herbicides were not detectable in water samples from one well, but in another well alachlor was detected at levels higher than 0.1 ppb. In soil, residues varied in the different fields and were in some cases higher than $0.1\,\mu g\,g^{-1}$.

An ethanesulfonic acid metabolite of metolachlor was identified in soil sample extracts by FABMS and FABMS/MS. A dissipation study revealed that ethanesulfonic acid is formed in soil under field conditions corresponding to a decrease in the concentration of the metolachlor.[188]

6.7 Oximes

Several analytical methods have been described for determination of alloxydim sodium, sethoxydim and its major active metabolites and clethoxidim.[5,124,125] Results obtained after application to residue determination in real samples are not reported.

6.8 Triazoles

An HPLC method with amperometric detection was described for determining residue levels of amitrole in drinking and groundwater. Samples with concentrations up to 1 ppb can be injected directly. When a simple evaporation enrichment step is used, the limit of determination is 0.1 ppb. If the method is applied to groundwater samples, no interference from co-eluting constituents appears in the chromatograms.[129] Another method using a coulometric array detector was also applied to tap and well water samples. Concentrations of amitrole down to $0.1\,\mu g\,L^{-1}$ can be determined without any enrichment steps. Several well water samples were investigated. Amitrole was not detectable.[131]

Amitrole can be extracted with ethanol, adsorbed on resin and desorbed with ammonia. After acetylation with acetic anhydride and cleanup over a Sep-Pack™ silica cartridge, the amitrole-acetyl derivative was determined by GC with FPD (flame photometric detection) in plant tissues and sandy soils. The method was used for screening the abuse of amitrole on vegetation growing on sandy soils. Over a period of more than one year a wide variety of weeds was analyzed.[133]

6.9 Pyridine-based Molecules

Thiazopyr residues have been determined in soil, grass weed and seedlings of woody plants after extraction with ethyl acetate, cleanup on a Florisil™ column and determination by GC/NPD and confirmation by GC/MS with ion trap detection. The proposed method was applied to the determination of the herbicide level in treated soil and plant samples.[135] The concentration range was $0.2-1\,ng\,g^{-1}$.

7 CONCLUSIONS

Miscellaneous pesticides are mainly polar compounds. For this reason, HPLC is the preferred technique for their separation and determination. However, complicated derivatization schemes are still used to enhance sensitivity and selectivity. These derivatization reactions present several problems when environmental analyses are performed or many samples are processed because they are time-consuming and give rise to interferences caused by the reagents and endogenous compounds of the matrices.

Best extraction methods should be used in order to obtain better separation of the endogenous interference compounds from the matrix and better sensitivity. Extraction methods using SPE are rarely employed in the analysis of miscellaneous pesticides. The use of these methods would make it possible to incorporate on-line extraction procedures, and to include these pesticides in the general multiresidue systems employed to determine a wide range of pesticide varieties from several matrices.

The development of modern techniques will facilitate application to real samples, monitor the presence of the pesticides in the environment and establish their persistence, fate, degradation and risk on the basis of real field data.

Contamination of water by pesticides is an important issue in many regions, posing problems in the environmental, water management and health sectors. To assess the extent of contamination of water, effective and properly designed analytical methods having sufficient sensitivity and accuracy are needed. However, no matter how excellent are the state-of-the-art analytical instrumentation and techniques applied, the data on trace concentrations of pesticides provided by the analytical system will be useless unless sufficient attention is given to sampling and sample preparation.

To collect a representative water sample for pesticide analysis, all sampling parameters must be selected properly. This refers predominantly to the selection of the appropriate sampling site, sampling technique and volume of the water sample. To prevent the sample matrix from any undesirable alterations during its transport from the sampling site to an analytical laboratory, physical (e.g. temperature, light intensity) and chemical/biochemical (e.g. pH, microbial growth) conditions must be under control, i.e. the sample must be preserved carefully. An efficient alternative to the transport of liquid water samples from the sampling point to the laboratory is on-site sorption of analytes on a solid phase. This minimizes the weight of transported samples and increases the stability of analytes.

The determination of trace concentrations of pesticides in water samples and the complexity of environmental matrices require the application of an efficient sample-handling procedure prior to separation and detection of these analytes. At present, liquid–liquid extraction (LLE) and solid-phase extraction (SPE) are the most frequently applied sample-handling techniques in the determination of pesticides in water. LLE is a traditional method that is still widely used in standardized methods. The increasing popularity of SPE is a result of its versatility and effectiveness and SPE is also preferred owing to the lower health risks.

The introduction of new sorbent materials, the development of automated sample-handling systems allowing unattended operation and newly emerging sample-handling techniques such as solid-phase microextraction (SPME) and membrane separation methods guarantee that sample preparation in pesticide analysis will remain a fertile area of development in the future.

1 INTRODUCTION

The extent of the application of pesticides reaches many thousands of tons per pesticide annually in many countries and the diversity of the insecticides, herbicides, growth regulators, fungicides and other applied substances is increasing rapidly. This extensive application has a negative impact on the quality of the environment. Because of their widespread use, pesticides are currently detected by determination of their residues in various environmental matrices, especially water.

To prevent water pollution by pesticides, precise information on their concentration levels in the water environment is needed. Owing to the diversity of pesticides and their low concentrations in water, the acquisition of this information requires the development of effective and properly designed analytical methods. The initial part of any of these methods comprises sampling and sample preservation and preparation. While in the past the importance of these initial steps has often been neglected, it is now clear that any mistake that occurs in collecting and processing a water sample can lead to substantial errors in the final data, regardless of the excellent performance of the state-of-the-art analytical technique that may be applied subsequently. Moreover, the results of a survey among analysts indicated that, for all respondents, two-thirds of the analysis time was spent on collection and preparation of the sample.[1] Therefore, it is clear that sample collection and handling deserves the attention of any water analyst who is trying to increase the throughput of methods used and to improve the overall performance of the analyses performed.

2 SAMPLING AND SAMPLE PRESERVATION

2.1 Sampling Site

The sampling site must be selected with respect to the objectives of a monitoring program or a survey. Thus, the overall monitoring strategy predetermines the choice of profiles in water streams or the number and/or the depth of the monitoring wells.

For instance, if the objective is to monitor transboundary pollution of the water stream, the location should be as close as possible to the border. If the objective is to assess the quality of water used for drinking-water production, the sampling site should be positioned close to the intake. The number and location of sampling stations for groundwater monitoring is a function of the objectives and scale of assessment (background or trend monitoring, emergency surveys around a spill, operational surveillance of the quality of potable water resources), the hydrogeological complexity and economic considerations.

In all those cases it must be assured that the location is suitable for taking representative samples with due regard for the objective of the sampling. Furthermore, to assure representativeness of the sample, it is recommended that replicate samples be taken occasionally to determine temporal and spatial variability. A thorough discussion on monitoring strategies is beyond the scope of this article and can be found in various manuals.[2–4]

2.2 Sample Volume

Sample volume depends on the number of analyses to be performed and on the technical requirements of a particular analysis. The volume of the water sample required for a single analysis of pesticides usually ranges from tens of milliliters up to 1–2 L, depending on the methodology applied. Traditional gas chromatography (GC) or high-performance liquid chromatography (HPLC) methods, in which an aliquot of the extract of the water sample is analyzed, require processing of a large volume of water (500 mL to 2 L) in order to reach the desired sensitivity. For modern SPE procedures, several hundred milliliters of water sample usually suffice. Introduction of highly sensitive detectors, on-line SPE techniques and large-volume injection possibilities permitted the reduction of the sample volume required for one analysis down to tens or even units of milliliters.

The total volume of water sample to be collected from the sampling site depends on the total number of analytes to be analyzed. Hence, theoretically, it can vary from 10 mL when, e.g. atrazine in water is to be determined using an on-line SPE/HPLC method to 10 L and more when a complete pesticide survey is to be carried out using standard methods employing LLE. To cover a large range of pesticides requires the application of a large number of different target methods, which makes complex screening laborious. A solution is the use of a suitable combination of methods covering as much of the pesticide range as possible. This approach has been used in a National Pesticide Survey performed in the USA where seven analytical methods were used to cover more than 100 pesticides of interest.[5]

2.3 Sampling

In general, the type of sampling depends on the goal of the monitoring program and differs for river water, reservoirs, groundwater, rainwater, wastewater, drinking water or pore water from the unsaturated zone. In river waters the sampling methods are usually based on bottle collection or water pump systems. When a homogeneous reach of a stream is monitored, the collection of samples in a single vertical mode may be sufficient. For small streams a grab sample taken at the centroid of flow is usually adequate.

For sampling profiles located on a nonhomogeneous reach of a river or stream, it is necessary to sample the cross-section of the river or stream at a specified number of points and depths. In principle, the cross-section has to be checked for homogeneity, analyzing a minimum of three locations within the cross-section, the left and right banks and the center of the river. Vertical homogeneity should also be checked. Sampling in streams should be normally performed at a depth of 0.3–1.0 m. Surface sampling is employed when there is a need to collect the heterogeneous matter floating on the river surface.

A similar situation is encountered in reservoirs, where the sampling design must take into account the vertical stratification. The presence of anaerobic conditions in the lower layers and algal growth in the surface layers leads to the establishment of specific distribution of physicochemical parameters in water influencing the stability and behavior of dissolved pesticides. Therefore, along with the pesticide analysis, data on basic physicochemical parameters such as temperature, pH, conductivity, nitrates, ammonia and oxygen should also be collected.

For sampling of groundwater, different kinds of pumps withdrawing the water from the boreholes or wells are used. Such discharge samples are normally collected in bottles from a well-head tap or directly from a pump outflow. In some cases grab sampling from nonpumping boreholes is also possible. The most common method of unsaturated zone sampling is by suction or tension. When taking samples from pump discharge, it must be ensured that the sample is representative of hydrochemical conditions in the aquifer, rather than those in the well.

In the case of public supply or irrigation wells which are operating continuously (or at least for long periods) at high discharge rates, it is relatively easy to collect a sample after a sufficiently long period of pumping to be certain that the water has been drawn from the aquifer rather than from within the well itself. If, however, specialist sampling pumps with low discharge rates are used to sample nonpumping observation wells, then purging the well of standing water is required before sampling.[6] It is often recommended to purge the water by removing 3–10 well volumes. It is also advised to measure continuously selected physicochemical parameters (pH, conductivity, temperature) to detect when stable conditions have been reached, indicating that the required high proportion of aquifer water is being drawn.

Even for one particular matrix the type of sampling can vary depending on the character of the information that is to be obtained from the monitoring. There are principally two types of samples: grab samples and composite samples. A grab sample is taken at a selected location and time, and then analyzed for pesticides. The collection of grab samples is appropriate when it is desired (i) to characterize water quality at a particular time and location, (ii) to provide information about minima and maxima and (iii) to analyze parameters which can be subject to change. A composite sample is obtained by mixing several discrete samples of equal or weighted volumes collected at regular time intervals in one container, which is subsequently analyzed for the parameters of interest. Instead of discrete sampling the water sample can be pumped continuously and required volumes of the sample for the analysis can be abstracted from the total bulk. Continuous sampling is advantageous in the case of automated monitoring systems. The selection of an appropriate sampling strategy has a considerable effect on the information output from a monitoring campaign. Especially for pesticides with seasonal occurrence it is very important to determine a suitable frequency and overall scheme of sampling, otherwise large deviations in the assessment of annual mean concentrations can result.[7]

To ensure that the collected water sample is a real representative of the sampled site and to avoid the detection of false positives, strict quality-control principles should be followed. These principles include qualification of sampling staff, checking for purity of sampling containers and collecting field blanks and field check samples. The use of duplicate samples for checking of sample stability and for eliminating random sampling errors is highly advisable.

2.4 Preservation of Water Samples

Preservation of the sample during transport and storage depends on the type of pesticides to be analyzed. In principle, we have to prevent any potential means of losses of analytes from the liquid phase, such as transfer to the gaseous phase (evaporation), transfer to the solid phase (adsorption on the container walls), hydrolysis, photodegradation and biodegradation. The losses due to analyte evaporation are not a critical issue for most pesticides. In any case, the storage of the water sample at 4 °C, minimization of the volume of the gaseous phase in the container and the use of gas-tight caps is recommended. Hydrophobic pesticides can be easily adsorbed on polymer surfaces. From an aqueous sample containing highly lipophilic organic compounds that are stored in a common plastic bottle, more than 90% of these compounds can be adsorbed within 24 h. Therefore, the storage of water samples in plastic containers must be avoided and the use of glass vessels only is recommended. Many modern polar pesticides can easily hydrolyse when the pH reaches a certain critical value. Hence it is necessary to maintain the pH at a desired value using a buffer solution or, usually in the case of acidic compounds, simply by acidifying the water sample. Keeping the samples in the dark and using amber-glass sample containers when available should prevent photolysis of the analytes. The presence of bioorganisms in water leads to biodegradation of dissolved pesticides. To suppress the biological activity of the aqueous environment, biodegradation inhibitors such as $HgCl_2$ are used.

Most standardized methods recommend reducing the time of storage of the water sample to a minimum and performing the extraction as soon as possible. Storage periods that are usually officially suggested range from 7 to 14 days. In the United States Environmental Protection Agency (USEPA) National Pesticide Survey, thorough analyte stability studies of both well water samples and final extracts were performed.[5] The primary focus of these studies was to demonstrate the stability of analytes for the maximum sample and extract holding times that would be permitted during the survey. Up to 100% loss was observed for 26 out of the 147 pesticides spiked into well water samples which had been biologically inhibited and stored at 4 °C for 14 days. The same pesticides generally remained stable in stored sample extracts.

An alternative to the transport of liquid samples is the on-site sorption of analytes on the solid phase, which minimizes the weight of transported samples and increases the stability of analytes. In many cases, the transfer of groundwater samples from an anaerobic aquifer to an aerobic environment may initiate oxidation or biodegradation of organic compounds, which may continue during the transport. Also, when taking a sample from an aerobic environment, photodegradation and biodegradation processes can alter the composition of the aqueous sample irreversibly. Using sorption

on a sorbent, analyte evaporation is minimized and adsorption on the container walls is avoided. Binding of molecules of the organic compounds to the active sites on the sorbent surface slows undesirable changes in their quality and quantity. Green and LePape[8] observed that XAD-2 macroreticular resin and octadecyl-bonded silica (C_{18}) had a preservative effect, which prevented the breakdown of sorbed hydrocarbons by bacteria. Hydrocarbons stored on these solid phases for periods of up to 100 days in the presence of an oleophilic bacterial population showed no evidence of biological degradation. In contrast, hydrocarbons stored in water samples containing the same bacteria showed pronounced degradation over much shorter storage periods. These authors suggested that the preservative effect resulted from trapping the organic compounds in the adsorbent lattice structure. The pores of XAD-2 or silica gel were smaller than bacteria, hence, the hydrocarbons were protected from bacterial attack. The stability of 34 selected pesticides extracted from water on to a graphitized carbon black (GCB) surface was evaluated under various storage conditions.[9] The best results were obtained by first minimizing the water content in the GCB extraction cartridge by a suitable methanol washing and freezing the cartridge. Under these conditions and over a storage period of 3 weeks the stability of pesticides extracted from four river water samples on to the GCB surface was assessed and compared with that in water at 4 °C with and without an inhibitor of biological degradation such as mercuric chloride. The results indicated that storage on the GCB material was a far better preservation procedure than storage in water at 4 °C. Several of the pesticides considered were completely degraded when stored in water in the presence of $HgCl_2$. Similarly to disposable off-line SPE cartridges, SPE precolumns were also tested for analyte storage possibilities. The stability of 19 organophosphorus pesticides was investigated using precolumns from the Prospekt (automated on-line SPE) system packed with C_{18} and stored under different conditions.[10] This study demonstrated that many organophosphorus pesticides that showed instability problems in water matrices were stable in disposable SPE precolumns for a period of up to 8 months at −20 °C. Similar cartridges were also used for the investigation of the stability of different groups of polar pesticides (triazines, phenylureas, carbamates and chlorinated phenols) sorbed on polymer sorbents from water samples.[11] The results showed the stability of most of the tested pesticides stored in cartridges for 7 weeks at the laboratory temperature or in a refrigerator. In Figure 1 it can be seen that except for carbaryl the recoveries of all tested pesticides were in the range 80–120% within 7 weeks of storage, which is an acceptable variance in organic trace analysis. The differences between stability of analytes when stored on a wet or silica gel-dried sorbent were negligible. The pH value of the water sample had a significant influence on the stability of only those compounds

Figure 1 Stability of pesticides sorbed from spiked tap water on to polymer cartridges that were stored wet in a refrigerator at 4–5 °C. Stability is expressed as the change of chromatographic peak area with time.

which had acid–base properties. The results obtained with surface water were similar to those obtained with tapwater. Also, a new SPE material, membrane extraction disks, was found to be a good preservation medium for pesticides.[12] The stability of triazines and acetanilides on these disks at −20 °C for 3 months, during which there was no evidence of degradation, indicated the feasibility of storage under these conditions. In general, in all of these stability investigations SPE was confirmed to be a suitable sample-handling technique when long-term preservation of analytes prior to the analysis was required.

3 SAMPLE HANDLING

Trace concentrations of organic analytes in water samples and the complexity of environmental matrices require the application of an appropriate sample-handling procedure prior to the separation and detection of these analytes. As has already been mentioned earlier, for contemporary environmental analysis it is characteristic that highly efficient separation and detection systems are often coupled with laborious and time-consuming sample-handling procedures which limit the sample throughput and hence the overall performance of the method.[1] Hence, at present, sample handling is considered to be the weakest point in environmental chromatographic analysis. The methods of and approaches to the sample handling of pesticides in the aquatic environment have already been thoroughly reviewed by Barceló and Hennion[13] and related reviews can also be found elsewhere.[14–17]

The major reasons for the preparation of water samples prior to pesticide analysis are

- preconcentration of analytes in order to enrich the sample with traces of the analytes;
- removal or reduction of compounds that interfere in the separation and/or detection steps;
- transfer of analytes into a homogeneous liquid matrix amenable to chromatographic analysis.

In most cases the preconcentration factors required for the efficient analysis of pesticides at the environmentally relevant levels are 100–10 000. In addition, a sample-handling procedure must be sufficiently robust to provide reproducible data for different aqueous matrices with various properties. The selected sample-handling strategy usually depends on the aim of the analysis and on the information expected, i.e. whether the analyst wants to detect one or several particular compounds of interest (target analysis) or if a multiresidue screening of a wide range of pesticides is required. In target analysis, the sample-handling step employs more selective procedures and media and more attention is paid to cleanup techniques. In screening analysis, nonselective procedures are usually preferred and, when necessary, a combination of several sample-handling techniques can be applied simultaneously. For example, during a long-term international program on river pollution identification that was performed in the Nitra river basin,[18] the simultaneous use of two LLE procedures along with an SPE method was performed to increase the ''analysis window'' as much as possible so that most of the organic pollutants present in the river water could be detected.

The complexity of a sample-handling procedure to be employed depends also on the type and level of the separation and detection system applied for this analysis. The use of a relatively nonselective detector or a chromatographic system with a low separation power in a target method requires the application of a selective trace enrichment procedure. On the other hand, a selective and sensitive detector used with a good separation system provides acceptable results even when a very simple sample-handling scheme is applied.

Nowadays, LLE and SPE are the most frequently applied sample-handling techniques in the determination of pesticides in water. The prevalence of LLE applications in environmental analysis in the past resulted from the hydrophobic character of pesticides listed on the priority pollutant lists at that time and also from the absence of an equally suitable and efficient technique. At present, LLE is still widely used in standardized methods for pesticide analysis, primarily those used for nonpolar pesticides. It is often preferred owing to the availability of standardized procedures and good descriptions in the analytical literature.

The increasing popularity of SPE is due not only to its obvious advantages over LLE (minimized consumption of organic solvents, no emulsion formation, reduced contact of the analyst with potentially toxic substances) but also to gradual refinements of this procedure which minimize its original drawbacks. The introduction of membrane extraction disks increased the speed of the preconcentration and the growing production of SPE materials lowered their prices. A wide choice of newly developed materials makes SPE perfectly suitable to cope with the growing variability of modern pesticides. At present, the major factors stimulating the preference of the use of SPE in water analysis are the possibility of automation, sample storage and preservation ability and a high potential in offering solutions for complex preseparation schemes.

The theoretical background of LLE and SPE is based on similar principles of the interphase distribution of a solute in a two-phase system. The distribution of a solute in such a two-phase system (liquid–liquid or liquid–solid)

is governed by the affinities of the solute to these phases and it is characterized by a distribution constant. In LLE, the transport of solutes from an aqueous phase into an organic solvent immiscible with water depends mostly on the hydrophobicity of the solute and its solubility in the solvent. In this case the preconcentration is carried out as a one-step transfer of the solute from water to an organic solvent. After equilibrium has been reached, an aliquot of the organic solvent is introduced into an analyzer. However, when needed, the solutes can be redissolved in another suitable solvent.

On the other hand, most SPE procedures comprise two-step transfer of the solute. First, the solute is sorbed from water on the solid surface of a sorbent or in the stationary phase bound to this surface and, subsequently, the solute is eluted with an appropriate solvent (or thermally desorbed into the gas chromatograph). Here, the choice of a suitable sorbent (i.e. the selection of strength of interactions responsible for binding the solute on the solid phase) and the choice of eluting solvent or thermal desorption conditions (i.e. the energy needed for breaking of the bonds) must be properly tuned to obtain a quantitative preconcentration.

3.1 Liquid–Liquid Extraction

In the 1960s and 1970s, the attention of environmental scientists was focused mostly on nonpolar pesticides which, thanks to the extensive implementation of electron-capture detection (ECD) in analytical practice, were found to be ubiquitous and owing to their accumulation potential they were recognized as a serious threat to the environment. Despite the excellent sensitivity of ECD, the preconcentration step was needed to reach low nanogram per liter levels, as was required by environmental standards. The strongly hydrophobic character of most of those compounds was a prerequisite for the choice of LLE as a preferred preconcentration technique that gave satisfactory recoveries for nonpolar pesticides.

Most of the classical preconcentration methods employing LLE have a relatively similar pattern: a water sample is extracted two or three times with a small volume (usually 10–50 mL) of an organic solvent (hexane, heptane, cyclohexane, methylene chloride, Freon, etc.) and the extracts (plus the solvent used for rinsing the internal surface of the glassware used for the extraction) are dried with purified sodium sulfate, filtered, evaporated either to dryness or to a volume usually under 1 mL and redissolved in a small volume of the solvent compatible with a selected chromatographic technique. This general pattern can, naturally, differ in various modifications and/or refinements of original methods but, in principle, three consecutive extraction steps with extraction volume ratios of approximately 1 : 30–40 are sufficient for removal of at least 90% of the hydrophobic compounds from water. To remove interfering compounds, the extract can be cleaned by percolation through a column packed with Florisil, alumina or another suitable sorbent.

Many different methods for pesticide analysis involving LLE have been published in the past but the actual strength of LLE is the availability of a number of standard procedures. Examples of standard methods for the determination of different groups of pesticides in water using LLE are shown in Table 1. Moreover, LLE is used not only in standardized methods for the determination of specific groups of pesticides but also in broad-range methods covering a large number of priority pollutants.[19] A great strength of common standardized LLE methods is that in addition to their standard description needed to achieve status as an official method, also the results of their interlaboratory validation can be found in the literature.[20,21] These collaborative studies help in judging the acceptability of a particular method by characterizing its multilaboratory performance in terms of recovery, overall and single analyst precision and the effect of water type on recovery and precision. The availability of the results from an interlaboratory validation supports the reliability of a tested method.

Even though it may seem that in the field of LLE everything has been investigated and solved, there are still new approaches to be studied. The use of a Goulden large-sample extractor was tested to reach DLs in the low nanogram per liter range[22] and this technique was presented as an alternative for SPE. The general strategy for multiresidue analysis of polar pesticides in groundwater using LLE with methylene chloride was published by Hoogendoorn et al.[23,24] The extracts were cleaned up on-line by means of column switching and subsequently analyzed by step-gradient elution. This approach was found to be powerful for the simultaneous assay of polar pesticides.

The use of LLE also simplifies the problem of the determination of the total content of a hydrophobic organic compound in a water environment. This problem is relevant especially for surface-water samples with a high content of suspended solids. In an LLE procedure, an organic solvent extracts hydrophobic analytes from both the aqueous solution and solid particles suspended in the water. Rinsing of the glassware minimizes the losses of analytes caused by adsorption on the glassware surface. Thus, the analytes present in the water sample are quantitatively recovered into the extract. Using an SPE procedure for handling of such heterogeneous water samples usually requires filtration through a membrane filter prior to an extraction. Therefore, the result of such SPE analysis provides information only on the content of an analyte dissolved in the aqueous phase. Also, if no filtration was applied prior to SPE preconcentration, the analytes

Table 1 Examples of preservation and handling of water samples in standardized methods for pesticide analysis employing LLE

Method[a]	Sample preservation	Extraction	Separation and detection[b]	Method DL ($\mu g L^{-1}$)
EPA 505 Organohalide pesticides	14 days (heptachlor 7 days), 4 °C	Extraction of sample with 2 mL of hexane	GC/ECD	0.002–6.8
EPA 507 Nitrogen- and phosphorus-containing pesticides	10 mg L^{-1} $HgCl_2$, 4 °C in the dark, 14 days only for some analytes, immediate analysis recommended	Extraction with methylene chloride, concentration of extract to 5 mL after substitution with methyl *tert*-butyl ether	GC/NPD	0.075–5
EPA 508 Chlorinated pesticides	10 mg L^{-1} $HgCl_2$, 4 °C, 7 days, immediate analysis recommended	Extraction with methylene chloride, concentration of extract to 5 mL after substitution with methyl *tert*-butyl ether	GC/ECD	0.0015–5
EPA 515.1 Chlorinated acids	10 mg L^{-1} $HgCl_2$, 4 °C in the dark, 14 days	Hydrolysis by adjustment of water sample to pH 12, solvent wash, acidification, extraction with diethyl ether, esterification using diazomethane	GC/ECD	0.02–1.3
EN ISO 6468 Organochlorine insecticides	4 °C in the dark, 24 h	Extraction with an organic solvent (hexane, heptane or petroleum ether), concentration of the extract to 1 mL	GC/ECD	0.001–0.01
USGS O-1104-83 Organochlorine and organo-phosphorus compounds	4 °C	Hexane, evaporation to 0.5 mL	GC/ECD	0.01
USGS O-1105-83 Chlorophenoxy acids	pH 2, 4 °C	Extraction with diethyl ether or methyl *tert*-butyl ether. Hydrolysis to free acids, methylation with boron trifluoride–methanol and purification using adsorption chromatography	GC/ECD	0.01
USGS O-3106-83 Triazines	–	Extraction with methylene chloride, adjustment to pH 7 to 9. Optional cleanup on alumina	GC/NPD	0.1
USGS 3107-83 Carbamates	–	Extraction with methylene chloride, evaporation to 1 mL, redissolution in acetonitrile	HPLC/UV	2.0
ASTM 6630 Organochlorine pesticides	4 °C, 7 days	Extraction with a mixture of methylene chloride and hexane or diethyl ether and hexane	GC/ECD	0.003–0.24
ASTM 6640 Chlorophenoxy acids	–	Extraction of acidified sample with diethyl ether, hydrolysis, esterification	GC/ECD	0.002–0.01

bound to suspended solids can hardly be trapped on the sorbent in the SPE cartridge and, therefore, they are lost for the analysis. The distribution of the analyte between the solid and aqueous phases depends on its hydrophobicity and its loss will increase with decreasing polarity.

3.2 Solid-phase Extraction

SPE, which has been developed intensively in recent decades, has become a powerful alternative technique to LLE owing to its simplicity, flexibility and high sample

throughput. Additional advantages include reduction of toxic solvent consumption and greater health safety. An overview of the advantages of SPE over LLE in water analysis can be found in the literature.[13–15,25] The results of experimental comparative tests have shown that a performance comparable to that of LLE could be achieved using SPE.[26–31]

The basic principle of SPE is the transfer of analytes from the aqueous phase to the active sites of the adjacent solid phase. This transfer is stimulated by the selection of appropriate operational conditions in the system of three major components, water (liquid phase)–sorbent–analyte. After the replacement of the water by a suitable liquid phase in this system, the analyte can be desorbed from the sorbent and further analyzed. Usually, the SPE process is carried out in the column and is often referred to as low-performance liquid chromatography.

Many factors influence the efficiency of the SPE process, the two most important being capacity and retention. An insufficient capacity of the sorbent surface can cause its overloading and, consequently, earlier breakthrough of analytes. However, this situation is considered not to be very likely owing to the low concentrations of organic compounds in treated water samples and the relatively high sorption capacities of applied sorbents. The more critical factor is the retention of analytes, which should be a maximum in the water–sorbent–analyte system and a minimum in the eluent–sorbent–analyte system. The existence of these two contradictory demands on the strength of the sorbent–analyte interactions leads to the necessity to make a compromise during the selection of working conditions for sorption and desorption so as to obtain an optimum preconcentration.

A typical sequence of SPE includes the following steps: activation of the sorbent (wetting with a suitable solvent), conditioning (replacing of the activation solvent by the aqueous phase), percolation of the water sample, cleanup (removal of interfering components), drying of the sorbent bed, elution of accumulated analytes and regeneration of the sorbent [usually not recommended for disposable cartridges because of memory effects[32] and/or hysteresis effects[33]].

With respect to the system approach, two modes of SPE can be distinguished: off-line and on-line. In the on-line configuration, the SPE column output is connected directly to the analytical column, so that elution and separation of analytes are performed in one step. In the off-line configuration, the elution and separation of analytes are two separate steps. The chemistry and general principles are the same for both of these variants, but, the differences in their methodology are sometimes the reason for certain drawbacks or advantages of one or other of these approaches in a particular application.[34]

3.2.1 Off-line Solid-phase Extraction

The off-line approach is very simple and even though it can be easily performed using a home-made system, a number of vacuum manifolds for sample extraction and analyte elution are commercially available. Similarly to traditional LLE, off-line SPE is also becoming a part of standardized protocols.[35] In general, using an off-line configuration, high operational flexibility with regard to the selection of different materials and elution solvents is available. This approach allows the selective fractionation of the original sample and the simultaneous use of different separation and detection techniques for one sample extract. Asafu-Adjaye et al.[36] separated kepone from other pesticides by flushing the loaded SPE column with hexane, which eluted DDT (1,1,1-trichloro-2,2-bis[*p*-chlorophenyl]-ethane), DDE (1,1-dichloro-2,2-bis[*p*-chlorophenyl]-ethylene) and HCB (hexachlorobenzene). Kepone and its metabolites were subsequently eluted with a mixture of hexane and diethyl ether. Wells et al.[37] discussed SPE as the chromatographic technique to be used for the selective fractionation of wastewater effluents. An elution scheme incorporating water, methanol and methylene chloride for the fractionation of nonpolar organic toxicants using SPE was found to be effective for the separation and isolation of compounds with log K_{ow} values ranging from 2.5 to 7 from aqueous solutions and for toxicants from a sediment pore water sample.[38]

In addition to the fractionation possibility, off-line SPE is a good substitute for LLE in the preconcentration of pesticides with a large range of polarity. The efficiency of the preconcentration depends substantially on the selection of a suitable solid phase. Bonded silicas, polymers and carbon sorbents are the most frequently applied SPE materials in newly developed sample-handling procedures used for the determination of pesticides in water.[39,40] When needed, the combination of several SPE columns and the use of several eluting solvents can increase the efficiency of the SPE procedure. DiCorcia et al.[41] extracted phenoxyacetic acid herbicides from water using a miniaturized cartridge containing GCB in the top part and a silica-based strong anion exchanger in the bottom part. After the percolation of the water sample through this cartridge, the anion exchanger was activated with sodium acetate solution. The sorbed analytes were then transferred from the GCB to the anion exchanger with methylene chloride–methanol solvent mixture basified with sodium hydroxide. After washing, herbicides were desorbed from the anion exchanger with water–methanol containing trifluoroacetic acid and

potassium chloride. The DLs were in the parts per trillion (nanograms per liter) range. The use of off-line SPE in screening for pesticides in water requires simple instrumentation and provides low DLs owing to the possibility of partial evaporation of the eluate from the SPE cartridge. DiCorcia et al.[42] presented an off-line approach to monitoring a large group of pesticides in ground- and river water. The method incorporated a fractionation of analytes into basic and neutral compounds and acidic compounds, based on two different interaction mechanisms of GCB. Processing of large volumes of water (0.5–2 L) and evaporation of the eluates led to DLs lower than 0.1μg L^{-1} for most of the pesticides in this case.

The ease of manipulation with disposable SPE media is being further enhanced. In the 1990s, membrane extraction disks were introduced as an attractive kind of SPE material. These membranes consist of a fibrillated polytetrafluoroethylene (PTFE) matrix in which sorbents such as bonded silicas, polymers or ion exchangers are enmeshed. Owing to the internal structure of the disks, high flow rates of water sample can be achieved and a reduction of the recovery due to channelling is avoided. The easy manipulation with disks makes them suitable for quick testing methods. Owing to obvious benefits of their use, disks became the preferred media for Drinking Water Test Methods as defined by the USEPA.[43] In the determination of pesticides in water, the eluate from the disk can be injected into a GC system and, if necessary, derivatization of analytes can be performed prior to the injection.[44] For screening of a wide range of pesticides, the eluate can be analyzed by both GC and liquid chromatography (LC) systems simultaneously.[45]

3.2.2 On-line Solid-phase Extraction

The principle of the on-line approach is the direct transfer of adsorbed analytes from the SPE column to the analytical column by the mobile phase. Hence this approach is also called precolumn switching or precolumn technology. The principles and technical aspects of the on-line approach, especially for HPLC analyses, have been described thoroughly[13,34,46] and many applications have been published in environmental and in biomedical analysis.

A typical simple on-line system is shown in Figure 2. It consists of two circuits connected together by the switching valve. The aqueous sample is introduced to the precolumn by the pump in the low-pressure (preconcentration) circuit and, subsequently, the precolumn is switched to the high-pressure circuit where the analytes are eluted by the mobile phase directly into the analytical column. The sample volume applied usually ranges

Figure 2 Basic on-line SPE/HPLC set-up. 1 = HPLC pump for analytical mobile phase; 2 = sample pump; 3 = SPE precolumn; 4 = analytical column; 5 = HPLC detector; 6 = workstation with printer.

from 10 to 200 mL depending on the analytes and on the total organic load of the water sample. The internal volume of the precolumn ranges from several tens to several hundreds of microliters. In principle, sorbent material in the SPE precolumn should be identical with the packing material in the analytical column to prevent broadening of chromatographic peaks (band broadening). Therefore, owing to the prevalence of octadecylsilica LC columns, C_{18} is frequently used as a precolumn packing. C_{18} precolumns are sufficient for the preconcentration of compounds with low polarity but problems occur in case of polar analytes. In such case, a sorbent having stronger interactions with these analytes than a conventional C_{18} material should be used in the precolumn. If the precolumn containing more hydrophobic material is connected to a C_{18} analytical column, this will lead to additional band broadening. Hence, a compromise between sufficient retention in the precolumn and band broadening in the analytical column is needed. Styrene–divinylbenzene polymeric sorbent was found to be a good solution to this problem.[47–51] The particle size of the precolumn material should be the same as used in the analytical column; however, it is possible to use particles with a larger diameter when processing water samples with a high concentration of suspended solids to prevent problems with high back-pressure.

The need for continuous monitoring of water quality initiated the development of rapid screening on-line SPE/HPLC methods with diode-array ultraviolet detection (DAD/UV). The use of on-line systems for this purpose allowed rapid access to information on water quality and a relatively high frequency of sampling. Within the framework of an international Rhine Basin Program, an on-line SPE/LC/DAD/UV system capable of screening for a large range of pesticides with different polarities was tested for more than 50 pesticides[48] and then was fully automated and validated for the determination of 27 pesticides.[51] Similar on-line systems for broad-range determinations of pesticides in water were developed using membrane extraction disks as packing

of the precolumn.[52,53] An interesting option in this kind of application is the use of a bifunctional membrane extraction disk cartridge containing both C_{18} and cation-exchange disks.[54] The combination of SPE materials having different functionalities allowed the simultaneous determination of basic, neutral and acidic pesticides. On-line systems can be used also for preconcentration of more ''problematic'' compounds. To improve the preconcentration efficiency for pyrethroid insecticides having both hydrophobic and hydrophilic behavior, both breakthrough on the precolumn and adsorption on the inner walls and surfaces were prevented by adding a neutral surfactant to the aqueous sample. The developed method involving micelle-mediated preconcentration was tested for surface water analysis and the whole system was found to be robust and to give good and repeatable results.[55]

To increase the functionality of the on-line SPE system, a more sophisticated scheme than that displayed in Figure 2 can be designed. For the preconcentration and fractionation of organic pollutants in industrial effluents, Nielen et al.[56] used three precolumns in series (C_{18}, PRP-1 and a cation exchanger) and eluted all precolumns separately. Brouwer et al.[57] connected two polymer (PLRP-S) precolumns in series and the outlet of each precolumn was directed on-line to a separate PLRP-S analytical column. While the first precolumn was operated in the reversed-phase mode, trace enrichment in the second precolumn was based on an ion-pairing mechanism. This allowed the preconcentration of acidic and basic compounds within one analysis. The same authors developed a similar system with one HPLC analytical column. In this system, they used as precolumns specially designed holders packed with membrane extraction disks.[58] A top state-of-the-art level in the development of sophisticated on-line systems was achieved by Slobodník et al.,[59] who developed an integrated system combining on-line SPE with LC and GC separation and detection by mass spectrometry (MS). The trace enrichment procedure was automated by a Prospekt cartridge-exchange/solvent-selection/valve-switching unit. After loading of the water sample, the precolumn was eluted on-line in two subsequent runs, first on to the gas chromatography/mass spectrometry (GC/MS) system and, next, onto the LC/DAD/UV/MS system using a particle beam interface (Figure 3). With this system, GC/MS, LC/DAD/UV and liquid chromatography/mass spectrometry (LC/MS) data on the same water sample could be obtained within 3 h, providing a large amount of structural information on unknown organic compounds present in the sample.

On-line coupling of SPE to GC is more complicated than to HPLC owing to problems with the liquid-phase/gas-phase interface. Even though this approach was already applied to the determination of pesticides in water in the 1980s,[60] more frequent use of on-line SPE/GC can be observed in the 1990s. An automatic SPE sample

preparation system was coupled on-line to capillary GC/ECD by means of a loop-type interface equipped with a solvent vapor exit.[61] Using SPE cartridges packed with silica for cleanup of the hexane extract of a water sample, it was possible to analyze concentrated surface water extracts for a group of organochlorine and pyrethroid insecticides present in the water at parts per trillion levels. This approach can be considered as a combination of LLE and SPE. If, in an SPE/GC system, the SPE cartridge is used for the direct accumulation of analytes from water, drying of the eluent prior to its injection into the GC system is desirable. For this purpose a small cartridge containing a suitable drying agent can be inserted between the SPE column and the GC system.[62] Introduction of programmable temperature vaporization (PTV) injectors in GC permitted the use of a GC liner packed with a solid support as an alternative to a SPE column. Thus, large volumes of water samples (up to 1 mL) can be introduced into a GC injector, water is separated in the liner and, after switching of a valve, compounds are thermally desorbed in the splitless mode by heating the PTV unit into the GC column.[63] The DLs obtained with such systems are in the sub-parts per billion range.

The application of a sophisticated cleanup procedure is not the only possibility for achieving a high selectivity. An alternative way is the use of a highly selective solid phase such as ion exchangers, metal-loaded sorbents or immunosorbents. The procedures utilizing these materials are rather complicated and require a skilled operator, but their efficiency and suitability for special target analyses have been demonstrated by different authors.[64–66]

A new development in the use of a solid phase for the preconcentration of pesticides from water is SPME, introduced and thoroughly developed by Pawliszyn et al.[67] SPME is based on a fiber coated with the stationary phase (e.g. polysiloxane or polyacrylate polymers) that is used for the direct extraction of organic compounds from water by dipping the fiber into the water sample. After sorption, the fiber is transferred into the heated injector of a gas chromatograph where the organic compounds are thermally desorbed from the stationary phase. This technique is becoming popular, as it is fast, sensitive, inexpensive, portable and solvent-free. Numerous applications of SPME in water analysis were reviewed by Eisert and Levsen[68] and SPME was found to be very attractive for routine use even though it still represents an exciting field of research.

3.3 Other Sample-handling Methods

Apart from LLE and SPE, only a few techniques based mostly on membrane and electromigration processes have received the attention of environmental analysts for handling of aqueous samples.

A supported liquid membrane (SLM) is typically constructed by immobilizing an immiscible liquid within the pores of a microporous film. In principle, the immobilized liquid can be aqueous or organic and various materials such as PTFE, cellulose acetate and polypropylene can be used as a support. The sample preparation set-up can be coupled on-line to the chromatograph. The use of closed systems minimizes the risk of contamination and losses during sample-handling. Since the volumes of organic solvent used in such a system are very small ($<500\,\mu L$) and the same solvent volume is used for a large number of samples, it is possible to use solvents which are expensive and also considered hazardous in batch extractions. Dihexyl ether was used in a liquid membrane applied for sample preparation for the determination of sulfonylurea herbicides in aqueous samples.[69] The technique studied in this work utilized extraction and back-extraction in an automated flow system and was coupled on-line to an LC system. The extractor unit consisted of an immobilized liquid membrane, separating two aqueous phases. From the acidified donor phase the analytes were extracted into the organic solvent of the membrane. After traversing the membrane, they were back-extracted into an alkaline/neutral aqueous acceptor phase. The use of the precolumn technique made it possible to inject the total amount of the extracted analytes. A liquid membrane device was also used for continuous sampling from a water stream in an integrated field sampling method for MCPA. MCPA was transferred as an uncharged species from a donor phase to a stagnant acceptor phase where it was trapped in a buffer, permitting a high degree of enrichment.[70] The final determination was made by HPLC utilizing a precolumn instead of a sample loop in the injector. The method has been found to give values in good agreement with a technique based on batch extraction and GC with a DL of ca. 0.03 ppb.

Membrane-based techniques can be efficient not only for trace enrichment purposes but also for the removal of interferences. The potential of the on-line combination of dialysis for the removal of interfering humic substances from environmental samples and trace enrichment on a precolumn packed with C_{18} for the determination of polar pesticides by column LC with UV detection was investigated by van de Merbel et al.[71] using six phenylurea herbicides as model compounds. Using a planar dialysis membrane with a molecular weight cut-off value of 3.5 kDa and a sample of 1.2 mL, interfering humic substances were sufficiently removed to allow the automated determination of selected phenylureas at the 1 ppb level. The transport of ionizable compounds through membranes can be supported by application of a voltage. Basic considerations for analyte enrichment and recovery obtainable by electrodialysis as a sample treatment

method were presented by Debets et al.[72] A practical application of on-line electrodialysis for the treatment of natural waters prior to the column LC determination of polar pollutants was described by Groenewegen et al.[73] Another approach to sample-handling of water samples containing ionizable compounds is the use of electromigration techniques. On-line coupling of isotachophoretic pretreatment to capillary zone electrophoresis (CZE) allowed the determination of paraquat and diquat at nanomoles per liter levels in tap and surface water.[74] Isotachophoresis was also presented as a selective sample pretreatment technique for ionic substances prior to HPLC analysis.[75]

Supercritical fluid extraction (SFE) has been demonstrated to be a good method for preparation of solid samples. However, there is only a very limited number of papers dealing with direct SFE of aqueous samples and owing to experimental problems this approach does not seem very promising for the future.[76]

4 CONCLUSIONS

Sample preparation, for reasons mentioned in the Introduction, will remain a fertile area of development in the future. Reduction of time and costs needed for sample handling and reduction of the consumption of toxic solvents will be the leading factors supporting any progress in this area. Automation will save time and reduce errors. New approaches and new techniques will make sample handling safer and more effective. There will be the simultaneous development of both simple and fast preconcentration schemes for routine use in rapid standard methods and sophisticated procedures coping with the continuous development of modern polar pesticides. The growing interest in ecotoxicological assessment and biomonitoring will influence the prevailing ''chemical'' character of the preparation of water samples. Also, obviously, research in environmental pesticide analysis will be tightly bound to regulatory policies in environmental protection and any pushing of regulatory levels to lower values or introduction of new parameters to the ''Black Lists'' will further stimulate the development of sample-handling techniques, especially for polar hydrophilic analytes.

ABBREVIATIONS AND ACRONYMS

C_{18}	Octadecyl-bonded Silica
CZE	Capillary Zone Electrophoresis
DAD/UV	Diode-array Ultraviolet Detection

Owing to their widespread use in agriculture and urban weed control and because of their high mobility in the subsoil, polar pesticides such as phenoxy acids and other acidic pesticides have been especially considered as a potential source of groundwater contamination. In Europe, pesticide residues tolerances in drinking water were set by the European Union Commission to 100 ng L^{-1} for an individual compound and 500 ng L^{-1} for the sum of pesticide residues. These maximum tolerances constitute a real challenge to analysts working in the field of pesticide residue monitoring. In the following article, analytical methods for the multiresidue analysis of phenoxy acids and other acidic pesticides in environmental samples at trace level concentrations are presented. Analytical methods using capillary gas chromatography (GC), high-performance liquid chromatography (HPLC), capillary zone electrophoresis (CZE) and automated multiple development thin-layer chromatography (AMDTLC) are described. GC methods are most often used in routine analysis of acidic pesticides owing to their unrivaled advantages in separation power. GC methods can be used in multiresidue analysis of up to more than 50 analytes at trace level concentrations. Owing to their high polarity and low volatility, acidic pesticides are not directly amenable to GC analysis, thus suitable derivatization methods are required. The applicability and drawbacks of several derivatization methods are described in detail. GC can be used with various detection methods such as electron capture detection (ECD), nitrogen–phosphorus detection (NPD), atomic emission detection (AED) or mass spectrometry (MS). GC/MS (gas chromatography/mass spectrometry) or GC/MS/MS (tandem mass spectrometry) detection provides the highest possible level of confidence independent of the complexity of the environmental matrix from water or even soil samples. The highest selectivity and sensitivity is achieved in selected ion monitoring (SIM) or in selected reaction monitoring (SRM) mode. Progress in coupling of HPLC to MS has improved the possibilities of identification and confirmation of analytes at trace level concentrations using HPLC methods and new promising analytical approaches such as HPLC coupled to atmospheric pressure ionization (API) MS/MS will gain much importance in the future. Enantioselective separation of different chiral isomers of phenoxy acid pesticides can be achieved applying CZE or by applying GC or HPLC with special chiral phases.

In water analysis, conventional liquid–liquid extraction (LLE) has mostly been replaced by solid-phase extraction (SPE) methods to extract and enrich the analytes from the samples. Two standard operating procedures (SOPs) are presented as examples for the analysis of phenoxy acids and other acidic pesticides in environmental samples (water and soil). Detection limits down to the low nanogram per liter level or down to the low microgram per kilogram level can be achieved for water samples or soil samples, respectively. Several examples for the environmental analysis of actual samples show the performance and sensitivity of today's trace level multiresidue analysis.

1 INTRODUCTION

The occurrence of polar pesticides in the environment has become a subject of increased public concern. Owing to their widespread use in agriculture and urban weed control and because of their high mobility in the subsoil, polar pesticides such as phenoxy acids and other acidic pesticides have been especially considered as a potential source of groundwater contamination. Consequently, in many environmental investigations these pesticides are analyzed to check their concentration against the maximum tolerances of pesticide residues in drinking water.

In Europe, these tolerances were set by the European Union Commission[1] to 100 ng L^{-1} for an individual compound and 500 ng L^{-1} for the sum of pesticide

residues. These maximum tolerances constitute a real challenge to analysts working in the field of pesticide residue monitoring. Analytical routine methods have to guarantee high accuracy and reliability at trace level concentrations independent of the amount and composition of the environmental matrix. Because of their polar structures, extraction from environmental samples and their analysis are much more difficult for acidic pesticides than for nonpolar pesticides such as organochlorine or triazine pesticides such as DDT (2,2-bis(chlorophenyl)-1,1,1-trichloroethane) or atrazine. To lower the costs of routine analysis it is also desirable to determine as many analytes as possible at one time in one procedure applying only a few so-called multimethods.

In this article, analytical procedures are presented which fulfill all stated requirements enabling multiresidue analysis of up to 40 acidic pesticides at trace level concentrations in water or soil.

2 AGRICULTURAL USE AND IMPORTANCE

Phenoxy acid pesticides, also called phenoxy alkanoic acid pesticides, are selective herbicides developed in the 1940s in the course of attempts to synthesize analogs of the auxin, β-indoleacetic acid, which had been recognized as a natural plant growth regulator.[2] The common mode of action of auxin-type herbicides is to mimic natural auxin, β-indoleacetic acid, thereby producing an abnormal lethal growth. On the molecular scale, they influence the levels of RNA and DNA polymerase and enzymes that regulate

Table 1 Common names, IUPAC names, CAS numbers and properties of acidic pesticides mentioned in this chapter

Common name (**structure no.**)	CAS no.	Chemical name (IUPAC)	Compound class/use
Acifluorfen **(20)**	50594-66-6	5-(2-Chloro-α,α,α-trifluoro-*p*-tolyloxy)-2-nitrobenzoic acid	Diphenyl ether herbicide, protoporphyrinogen oxidase inhibitor
Benazolin **(21)**	3813-05-6	4-Chloro-2,3-dihydro-2-oxo-1,3-benzothiazol-3-yl-acetic acid	Arylacetic acid herbicide, auxin type
Bentazone **(10)**	25057-89-0	3-Isopropyl-1*H*-2,1,3-benzothiadiazin-4(3*H*)-one 2,2-dioxide	Benzothiadiazinone herbicide, photosynthetic electron transport inhibitor
Bromoxynil **(13)**	1689-84-5	3,5-Dibromo-4-hydroxybenzonitrile	Hydroxybenzonitrile herbicide, photosynthetic and respiratory electron transport inhibitor
Chloramben **(22)**	133-90-4	3-Amino-2,5-dichlorbenzoic acid	Benzoic acid herbicide, auxin type
Chlorfenac **(23)**[a]	20782-58-5	(2,3,6-Trichlorophenyl)acetic acid	Aryloxyalkanoic acid herbicide, plant growth regulator
Chloroxynil **(12)**[a]	1891-95-8	3,5-Dichloro-4-hydroxybenzonitrile	Hydroxybenzonitrile herbicide, photosynthetic and respiratory electron transport inhibitor
4-CPA **(1)**	122-88-3	*p*-Chlorophenoxyacetic acid	Aryloxyalkanoic acid herbicide, plant growth regulator
Clopyralid **(24)**	1702-17-6	3,6-Dichloropyridine-2-carboxylic acid	Pyridinecarboxylic acid herbicide, auxin type
2,4-D **(2)**	94-75-7	(2,4-Dichlorophenoxy)acetic acid	Aryloxyalkanoic acid herbicide, auxin type
2,4-DB **(3)**	94-82-6	(2,4-Dichlorophenoxy)butyric acid	Aryloxyalkanoic acid herbicide, auxin type
Dicamba **(25)**	1918-00-9	3,6-Dichloro-*o*-anisic acid	Arenecarboxylic acid herbicide, auxin type
Dichlorophen **(17)**	97-23-4	4,4′-Dichloro-2,2′-methylenediphenol	Chlorophenol fungicide

Table 1 (*continued*)

Common name (**structure no.**)	CAS no.	Chemical name (IUPAC)	Compound class/use
Dichlorprop **(4)**	120-36-5	2-(2,4-Dichlorophenoxy)propionic acid	2-Aryloxyalkanoic acid herbicide, auxin type
Dinoseb **(15)**	88-85-7	2-*sec*-Butyl-4,6-dinitrophenol	Dinitrophenol herbicide, respiratory electron transport inhibitor
DNOC **(16)**	543-52-1	4,6-Dinitro-*o*-cresole	Dinitrophenyl insecticide and herbicide, respiratory electron transport inhibitor
Endothal **(26)**	145-73-3	7-Oxabicyclo[2,2,1]heptane-2,3-dicarboxylic acid	Cyclohexane-1,2-dicarboxylic acid herbicide
Fenoprop **(5)**[a]	93-72-1	2-(2,4,5-Trichlorophenoxy)propionic acid	2-Aryloxyalkanoic acid herbicide, auxin type
Flamprop **(27)**	58667-63-3	*N*-benzoyl-*N*-(3-chloro-4-fluorophenyl)-DL-alanine	Arylalanine herbicide, fatty acid synthesis inhibitor
Fluazifop **(28)**	69335-91-7	2-[4-(5-Trifluoromethyl-2-pyridyloxy) phenoxy]propionic acid	2-(4-Aryloxyphenoxy) alkanoic acid herbicide, fatty acid synthesis inhibitor
Flurenol **(29)**	467-69-6	9-Hydroxyfluorene-9-carboxylic acid	Fluorene-9-carboxylic acid herbicide, plant growth regulator
Fluroxypyr **(30)**	69377-81-7	4-Amino-3,5-dichloro-6-fluoro-2-pyridyloxyacetic acid	Pyridyloxyacetic acid herbicide, auxin type
Fuberidazole **(11)**	3878-19-1	2-(2-Furyl)benzimidazole	Benzimidazole fungicide
Haloxyfop **(31)**	69806-34-4	2-[4-(3-Chloro-5-trifluoromethyl-2-pyridyloxy)phenoxy]propionic acid	2-(4-Aryloxyphenoxy) alkanoic acid herbicide, fatty acid synthesis inhibitor
Imazapyr **(36)**	81334-34-1	2-(4-Isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)nicotinic acid	Imidazolinone herbicide, branched chain amino acid synthesis inhibitor
4-Indol-3-yl-butyric acid **(35)**	133-32-4	4-Indol-3-yl-butyric acid	4-Indol-3-yl-butyric acid plant growth regulator
Indol-3-yl-acetic acid **(34)**	87-51-4	β-Indoleacetic acid	Indol-3-yl-acetic acid plant hormone
Ioxynil **(14)**	1689-83-4	4-Hydroxy-3,5-di-iodobenzonitrile	Hydroxybenzonitrile herbicide, photosynthetic and respiratory electron transport inhibitor
MCPA **(6)**	94-74-6	(4-Chloro-2-methylphenoxy)acetic acid	Aryloxyalkanoic acid herbicide, auxin type
MCPB **(7)**	94-81-5	4-(4-Chloro-2-methylphenoxy)butanoic acid	Aryloxyalkanoic acid herbicide, auxin type
Mecoprop **(8)**	7085-19-0	2-(4-Chloro-2-methylphenoxy)propionic acid	Aryloxyalkanoic acid herbicide, auxin type
2-(1-Naphthyl)acetic acid **(32)**	86-87-3	2-(1-Naphthyl)acetic acid	Arylacetic acid plant growth regulator
PCP **(18)**	608-93-5	Pentachlorophenol	Phenolic herbicide, fungicide and insecticide
2-Phenylphenol **(19)**	90-43-7	Biphenyl-2-ol	Phenolic fungicide
Picloram **(33)**	1918-02-1	4-Amino-3,5,6-trichloropyridine-2-carboxylic acid	Pyridinecarboxylic acid herbicide, auxin type
Quinchlorac **(37)**	84087-01-4	3,7-Dichloroquinoline-8-carboxylic acid	Quinolinecarboxylic acid herbicide, auxin type
Quinmerac **(38)**	90717-03-6	7-Chloro-3-methylquinoline-8-carboxylic acid	Quinolinecarboxylic acid herbicide, auxin type
2,4,5-T **(9)**	93-76-5	(2,4,5-Trichlorophenoxy)acetic acid	Aryloxyalkanoic acid herbicide, auxin type
2,3,6-TBA **(39)**	50-31-7	2,3,6-Trichlorobenzoic acid	Benzoic acid herbicide, auxin type
Triclopyr **(40)**	55335-06-3	3,5,6-Trichloro-2-pyridyloxyacetic acid	Pyridyloxyacetic acid herbicide, auxin type

normal growth and development processes.[2] Although phenoxy acids are the oldest group among the synthetic herbicides[3] they are still frequently used worldwide. In Germany, the phenoxy acids dichlorprop **(4)**, mecoprop **(8)**, 2,4-D ((2,4-dichlorophenoxy)acetic acid) **(2)** and MCPA ((4-chloro-2-methylphenoxy)acetic acid) **(6)** are among the most important agricultural pesticides.[4] In total, more than 1000 tonnes of phenoxy acid herbicides are applied annually in Germany.[4] Additionally, new polar herbicides have been developed and introduced in agriculture.

Some acidic pesticides can be determined in routine multimethods together with the phenoxy acids. The common names of all pesticides that can be analyzed with the analytical methods presented in this article are compiled in Table 1 together with their IUPAC (International Union of Pure and Applied Chemistry) names, CAS (Chemical Abstracts Service) numbers and their mode of action as pesticides. The structural formulae of all compounds are shown; **(1)** to **(9)** are phenoxyalkanoic acid herbicides, **(10)** to **(19)** are amide and phenolic pesticides and **(20)** to **(40)** are other acidic pesticides. The range of analytes includes many carboxylic acids and also two amides, namely bentazone **(10)** and fuberidazole **(11)**, and some phenolic pesticides such as bromoxynil **(13)** and ioxynil **(14)** which are frequently used in combination with phenoxy acid herbicides to broaden the range of weeds controlled.[5] As a whole, more than 40 acidic pesticides can be analyzed from all different kinds of water and soil samples using the methods described in this article.

3 INSTRUMENTAL ANALYSIS

Separation of the analytes from each other and from interfering matrix compounds is a prerequisite in environmental multiresidue analysis. Therefore, HPLC and capillary GC are the two favorite separation techniques in multiresidue analysis of acidic herbicides in water or soil samples. As will be discussed in detail in the following sections, both techniques have advantages and drawbacks when analyzing acidic pesticides. At the moment, GC methods in combination with MS have some advantages compared to HPLC or other GC methods and thus they are most frequently applied in all modern environmental laboratories. Nevertheless, there are some very promising new instruments, such as HPLC coupled to API/MS/MS. As prices for these sophisticated but still easy to use instruments are decreasing they will probably gain much more importance in environmental analysis of polar pesticides. Apart from GC and HPLC methods there are also other techniques which are used for the analysis of acidic pesticides. A modern variation of thin-layer chromatography (TLC) is the so-called AMDTLC which offers much higher separation power than conventional TLC methods. In combination with HPLC the separation power of both techniques can be enhanced remarkably,[6] but has not yet been applied to acidic pesticides. Methods applying CZE have some importance, especially when information about the distribution of different enantiomers of acidic pesticides in the environment is required. There are also some immunochemical methods which have been developed for the analysis of different phenoxy acid herbicides, such as 2,4-D **(2)**, 2,4,5-T **(9)**, mecoprop **(8)** and dichlorprop **(4)**.[7–20] Owing to their selectivity, the immunochemical assays are only suitable for single compound analysis. These methods often show some cross reactivities to chemically related compounds whenever these occur at higher concentrations in the samples. The cross reactivities are, however, not normally desirable and have to be suppressed to avoid false positive results. Thus, immunochemical methods may be used as rapid screening methods in environmental analysis but have not been included in this article describing multiresidue methods.

3.1 Capillary Gas Chromatography

Capillary GC is the analytical method with the greatest separation power and therefore the best suited to multiresidue analysis of pesticides from environmental samples. Automated GC analysis has become routine for environmental samples, with autosamplers carrying out automatic injection. There are many monographs about GC and GC/MS which describe the hardware, the techniques, potential interferences and applications in environmental analysis.[21–29] A major drawback of conventional GC analysis using hot split/splitless injection is that only small proportions of the samples (1–5 μL) can be introduced into the GC. Therefore, new large volume injection techniques have been developed[30–32] to enable the direct analysis of up to 1 mL of sample extracts to improve, if necessary, the detection limits of GC analysis. One technique, the programmed temperature vaporization (PTV) has been used for the analysis of acidic pesticides, as will be described in section 3.1.4.2.

The ease of coupling GC to highly sensitive detectors such as the ECD, the NPD or the flame photometric detector (FPD), and most importantly the subsequent coupling of GC to MS, further increased the prevalence of GC over other analytical techniques in trace level analysis of pesticides.[33] As will be described in sections 3.1.3.2, 3.1.3.3 and 3.1.3.4, the use of MS applying special acquisition and/or ionization techniques such as SIM, chemical ionization (CI) or MS/MS acquisition enables the analysis of pesticide residues at parts per billion (ppb)

or even parts per trillion (ppt) levels. GC/MS detection also provides the highest possible level of confidence independent of the complexity of the matrix from water or even soil samples. Another new and very interesting GC detector is the AED, which enables the element specific analysis of pesticide residues. Its performance in the determination of acidic pesticides will be described in section 3.1.4.2.

Because of their high polarity and low volatility, acidic pesticides are not directly amenable to GC analysis and have to be derivatized using suitable derivatizing agents. Many different derivatization methods have been described and will be discussed in the following section. The determination of these derivatives applying GC with ECD, NPD, AED or MS detection will be demonstrated in sections 3.1.2 to 3.1.4.

3.1.1 Derivatization Techniques

Methylation by diazomethane and derivatization using pentafluorobenzyl bromide (PFBBr) are most commonly used for the determination of phenoxy acids and other acidic pesticides by GC. Depending upon the individual analytical problem there are some other very interesting alternative derivatization techniques whose benefits, drawbacks and suitability for the different compound classes will be described in this section.

3.1.1.1 Alkylation to Methyl, Ethyl and Butyl Esters Methylation of phenoxy acid herbicides with methanol/sulfuric acid[34–36] is one of the classical and very reliable derivatization methods. Unfortunately, methylation of phenolic or amide pesticides is not possible using this procedure. Therefore, it has for the most part been substituted by diazomethane derivatization[37–50] which is also able to methylate compounds such as bromoxynil **(13)**, ioxynil **(14)** or bentazone **(10)** which are often integrated in multiple-residue methods in water analysis. *Caution: Diazomethane has to be handled carefully, because it is toxic and known to be a potent carcinogen and mutagen. Diazomethane may also explode when used inappropriately, especially at higher concentrations.* Recently, Rimmer et al.[51,52] described the analysis of six phenoxy acid herbicides using trimethylsilyldiazomethane, which is commercially available. Derivatization with trimethylsilyldiazomethane provides a less hazardous method for preparing the phenoxy acid methyl esters under milder conditions than with diazomethane.[51]

As long as only carboxylic pesticides are to be analyzed, alkylation with chloroformates[53] is an interesting alternative. Using commercially available methyl, ethyl or butyl chloroformates, it is very easy to produce the corresponding methyl, ethyl or butyl esters. It is thus possible to identify and confirm acidic pesticides using only one GC column and a conventional ECD as shown in section 3.1.2. Methyl esters may also be formed by derivatization with boron trifluoride–methanol[54–56] or methyl iodide.[57] Another interesting technique for the methylation of acidic pesticides is the intra-injector derivatization using trimethylsulfonium hydroxide (TMSH)[58] or trimethylanilinium hydroxide (TMAH).[59] These derivatizations proceed very quickly and easily, but may be problematic in quantification, especially when interfering matrix compounds are involved.

There is one common drawback with all the above alkyl derivatives: they show some problems in ECD detection of lower chlorinated analytes such as mecoprop **(8)**, MCPA **(6)** or MCPB **(7)**. Other acidic pesticides such as bentazone **(10)** or 2-(1-naphthyl)acetic acid **(32)** are not detected by the ECD at all. Thus, many recent methods recommend GC/MS detection for the analysis of the methyl derivatives. Some typical alkylation procedures are described in detail in the following sections.

Methylation with Methanol/Sulfuric Acid. This derivatization procedure is according to the German standard method.[34] An aliquot of a standard solution or sample extract dissolved in methanol (about 2 mL) is combined with 1 mL of sulfuric acid ($\rho(H_2SO_4) = 1.84\,g\,L^{-1}$) in a 10-mL volumetric flask. The reaction mixture is allowed to stand for 10 min. Then the volume is adjusted to 10 mL by adding distilled water. One milliliter of hexane is added to the mixture which is then vigorously shaken. A portion of 1–2 µL of the hexane layer is injected into the GC.

For suitable GC conditions see sections on Methylation with Diazomethane and Alkylation using Chloroformates below.

Methylation with Diazomethane. This derivatization procedure is according to the EPA (Environmental Protection Agency) and the German standard method.[47,37] A diazomethane solution in methyl *tert*-butyl ether (MTBE) is produced by using a diazomethane solution generator under a fume hood as reported in detail elsewhere.[37,60] *(Caution: Wear appropriate safety equipment to minimize skin contact and inhalation hazards. Avoid heat, because diazomethane is explosive near 90 °C.)* Before use, the diazomethane solution can be stored for a few days or weeks at 0–5 °C[47] or −18 °C.[37]

An aliquot of a standard solution or sample extract containing the acidic pesticides (e.g. 1 mL) is dried under a gentle stream of nitrogen in a reaction tube. A portion of 0.5 mL of the diazomethane solution is added to the extract. After addition of diazomethane solution the analyte extracts should turn and remain yellow for more than 2 min, otherwise the methylation procedure should be repeated. The reaction tubes are then sealed with stoppers and held at room temperature for 30 min under a fume hood. The unreacted diazomethane is destroyed by adding 0.1–0.2-g of silicic acid or by evaporation to

a defined volume >200 μL. The reaction tubes are then left to stand for approximately 20 min until evolution of nitrogen gas ceases. The extracts are adjusted to a defined volume by adding MTBE and injected (2 μL) directly or after a cleanup procedure using Florisil[47] into GC.

Suitable GC conditions[37,45] are as follows. Instrument: GC/ECD or GC/MS. Capillary column: HT-5 (SE-54) fused-silica capillary column, 25 m × 0.25 mm ID (inner dimensions), with a film thickness of 0.1 μm and hot splitless injection. Carrier gas: helium (0.8 bar). The oven temperature is held at 80 °C for 2 min following injection, then programmed at 20 °C min^{-1} to 160 °C, which is held for 4 min, then increased at 4 °C min^{-1} to 200 °C, followed by an increase of 25 °C min^{-1} to 260 °C and finally held for 3 min. Injection port, detector (ECD) or interface (MS) temperatures are set to 250 °C, 300 °C and 270 °C, respectively.

Alkylation using Chloroformates. This derivatization procedure is according to Butz and Stan.[53] An aliquot of a standard solution or sample extract (e.g. 1 mL) is dried under a gentle stream of nitrogen in a reaction tube. To obtain the ethyl esters the dried residue is dissolved in 100 μL of a reaction mixture containing acetonitrile, ethanol, water and pyridine (5:2:2:1 v/v) followed by 7 μL of ethyl chloroformate. To obtain the methyl esters the dried residue is dissolved in 100 μL of a reaction mixture containing acetonitrile, methanol, water and pyridine (2:2:7:1 v/v) followed by 7 μL of methyl chloroformate. To obtain the butyl esters the dried residue is dissolved in 100 μL of a reaction mixture containing acetonitrile, butanol, water and pyridine (2:2:6:1 v/v) followed by 7 μL of butyl chloroformate. Then the reaction tube is shaken gently against a pad for about 5 s to initiate the gas evolution. The solution is dried under a gentle stream of nitrogen and the residue is dissolved in 100 μL of toluene. A 1-μL portion of this solution is injected into the GC.

Suitable GC conditions[53] are as follows. Instrument: GC/ECD or GC/MS. Capillary column: HP-5 fused-silica capillary column, 25 m × 0.2 mm ID, with a film thickness of 0.32 μm and hot splitless injection with the split closed for 1 min. Carrier gas: helium. The oven temperature is held at 100 °C for 1 min following injection, then programmed at 30 °C min^{-1} to 150 °C, which is held for 2 min, then increased at 3 °C min^{-1} to 205 °C, followed by an increase of 10 °C min^{-1} to 260 °C and finally held for 25 min. Injection port, detector (ECD) or interface (MS) temperatures are set to 220 °C, 300 °C and 190 °C, respectively.

3.1.1.2 Alkylation Introducing Hetero Atoms Derivatization methods to form alkyl esters containing hetero atoms such as fluorine or chlorine have been developed to overcome the sensitivity problem of the ECD. Some of the resulting derivatives also have excellent mass spectrometric properties for trace level multiresidue analysis applying GC/MS with SIM programming (see section 3.1.3.2).

The formation of 2,2,2-trifluoroethyl,[61–63] 2-chloroethyl,[61] 2,2,2-trichloroethyl[61,64] and 2,2,3,3,3-pentafluoropropyl esters[64] of phenoxy acids has been described. In environmental analysis the formation of pentafluorobenzyl (PFB) esters by reaction with PFBBr has gained much importance.[28,64–79] PFB esters increase the sensitivity of ECD detection tremendously and they allow the determination of acidic pesticides independent of their substitution with chlorine. Derivatization with PFBBr enables the determination of phenoxy acid herbicides, other carboxylic acid pesticides, some phenolic pesticides and even amide pesticides such as bentazone or fuberidazole.[28,75,76]

Three different procedures for the formation of PFB esters have been reported. The classical procedure is performed using acetone as solvent and potassium carbonate as catalyst.[64–71,78] Heberer et al.[28,75,76] described an alternative procedure using toluene as solvent and triethylamine as basic catalyst. This procedure has some advantages when analyzing environmental samples because many interfering matrix compounds are excluded from GC before analysis.[28,76] Meiring et al.[73] described the phase-transfer-catalyzed derivatization of polar pesticides using tetrahexylammonium hydrogensulphate as complexing agent which transports the analytes from the aqueous layer into a dichloromethane layer where they are derivatized with PFBBr.

As shown in section 3.1.2, a major drawback of the PFB ester procedure is the large number of interfering substances in the extract from the environmental matrix when the extract is analyzed by GC/ECD.[28,64,75] The analysis of derivatized sample extracts by GC/ECD often requires time-consuming cleanup procedures.[64] Thus, the screening of these derivatives using GC/MS with SIM (see section 3.1.3.2) or using GC with AED, as shown in section 3.1.4.2, has great advantages compared to conventional GC/ECD methods. GC/MS with SIM enables the analysis of more than 40 acidic pesticides down to the low microgram or even nanogram per kilogram level in soil samples and down to the low nanogram per liter level in water samples, as will be shown in section 4.

Pentafluorobenzylation. A first derivatization procedure is according to Heberer et al.[28,75,76] An aliquot of a standard solution or sample extract (e.g. 1 mL) is dried under a gentle stream of nitrogen in a sample vial. A 200-μL portion of a PFBBr solution (100-μL PFBBr dissolved in 4.9-mL toluene) and 2-μL triethylamine are added to the residue. The vial is capped with a Teflon®-lined septum and the reaction mixture is heated for 1 h at 110 °C

simply by placing in a drying cabinet. The mixture is then cooled to room temperature, the vials are decapped and the solution containing the derivatized compounds is dried under a gentle stream of nitrogen. The residue is dissolved in 100 μL of toluene and 2 μL of this solution is injected into the GC/MS.

The second derivatization procedure is according to Gurka et al.[65] An aliquot of a standard solution or sample extract (e.g. 1 mL) is dried under a gentle stream of nitrogen in a sample tube. Four milliliters acetone, 30 μL of 10% K_2CO_3 in distilled water and 200 μL of 3% PFBBr in acetone are added to the residue. The tube is closed with a glass stopper and mixed on a vortex mixer. The tube is then heated for 3 h at 60 °C in a tube heater. The mixture is evaporated to 0.5 mL under a gentle stream of nitrogen. A 2-mL portion of hexane is added to the solution and evaporation is repeated to dryness at room temperature. The residue is dissolved in toluene–hexane (1 + 6) for column cleanup using silica columns topped with anhydrous Na_2SO_4. The column is prewetted with 5-mL hexane (let drain to top of sorbent) and the reaction mixture is transferred quantitatively to the top of the column. The column is then washed with 8 mL of toluene–hexane mixture (1 + 6) and the PFB derivatives are eluted with toluene–hexane (9 + 1) to collect 8.0 mL. An aliquot of this fraction is analyzed by GC/ECD or GC/MS.

Suitable GC conditions[28,75,76] are as follows. Instrument: GC/ECD, GC/AED or GC/MS. Capillary column: 25 m × 0.2 mm ID × 0.33 μm HP-5 capillary column fitted with a 1.5 m × 0.32 mm ID × 0.33 μm HP-5 precolumn. Carrier gas is helium (purity: 99.999%) set to a flow of 28 cm s^{-1} at the initial temperature. The oven temperature is held at 100 °C for 1 min following injection, then programmed at 30 °C min^{-1} to 150 °C, which is held for 1 min, then at 3 °C min^{-1} to 205 °C followed by 10 °C min^{-1} to 260 °C and finally held for 23 min. Injection port, detector (ECD) or interface (MS) temperatures are set to 230 °C, 300 °C and 250 °C, respectively. Samples are injected using hot splitless injection with the split closed for 0.9 min.

Trifluoroethylation. This derivatization procedure is according to Lee et al.[63] An aliquot of a standard solution or sample extract (e.g. 1 mL) is dried under a gentle stream of nitrogen in a Teflon®-capped vial. A 0.5-mL portion of sulfuric acid (analytical grade) and 1.0 mL of 2,2,2-trifluoroethanol are added to the vial. The vial is capped tightly, the mixture is gently swirled. The reaction is carried out in a water bath at 90 °C for 4 h. Then the vial is cooled down under flowing tap water. Deionized water (6 mL) and 2 mL of hexane are added to the vial which is then shaken vigorously. After separation of the two liquid phases, 1 mL of the hexane layer is transferred to a 10-mL volumetric flask and diluted to volume with hexane. A 2-μL portion of this solution is injected into the GC.

Suitable GC conditions[63] are as follows.

1. Instrument: GC/ECD. Capillary column: Rtx-35 fused-silica capillary column, 30 m × 0.53 mm ID, with a film thickness of 0.5 μm. Samples are injected using splitless injection. Carrier gas is helium, make-up gas 5% methane in argon. The oven temperature is held at 130 °C for 6 min following injection, then programmed at 30 °C min^{-1} to 160 °C, which is held for 5 min, then increased to 210 °C, which is held for 6 min followed by an increase to 260 °C and finally held for 3 min. Injection port and detector temperatures are set to 265 °C and 300 °C respectively.

2. Instrument: GC/MS. Capillary column: HP-5 fused-silica capillary column, 30 m × 0.25 mm ID, with a film thickness of 0.25 μm and splitless injection. Carrier gas is helium set to a head pressure of 90 kPa. The oven temperature is held at 80 °C for 3 min following injection, then programmed at 30 °C min^{-1} to 140 °C, which is held for 8 min, then increased to 210 °C, which is held for 5 min followed by an increase to 260 °C and finally held for 5 min. Injection port and interface temperatures are set to 230 °C and 280 °C respectively.

3.1.1.3 Silylation Silylation is probably the most versatile derivatization technique currently available to enhance GC performance by blocking protic sites.[80] Therefore, it is frequently used especially in clinical chemistry. The use of silylation reagents has, however, one major drawback; almost all of the reagents and the resulting derivatives are sensitive to the hydrolytic effects of moisture. Thus, for a long time silylation with (2-cyanoethyl)dimethyl(diethylamino)silane (CEDMSDEA) was the only described silylation procedure for the analysis of acidic pesticides.[81,82]

Another promising method is the derivatization of acidic pesticides with *N*-(*tert*-butyldimethylsilyl)-*N*-methyltrifluoroacetamide (MTBSTFA) forming their *tert*-butyldimethylsilyl (TBDMS) derivatives. The derivatization procedure is simple and rapid and, as shown in section 3.1.3.1, the resulting TBDMS derivatives exhibit characteristic EI (electron ionization) MS spectra. In contrast to other silylated derivatives they have proven to be stable for several days, even in the presence of moisture. The remarkable stability of the derivatives to hydrolysis can be explained by the sterical hindrance caused by the large tertiary butyl moiety which protects the silicon–oxygen bond from hydrolytic attack.[83] This method was successfully applied by Heberer and Stan[83] for the analysis of more than 50 substituted phenols including also six phenolic pesticides in water analysis. As presented here, this derivatization technique is also suitable

for the determination of other acidic pesticides, including all pesticides containing carboxylic acids. Unfortunately, amides such as bentazone **(10)** or fuberidazole **(11)** are not derivatized by this method.

Silylation with (2-Cyanoethyl)dimethyl(diethylamino)-silane. This derivatization procedure is according to Bertrand et al.[81,82] The preparation of the silylating reagent CEDMSDEA was published in 1986 by Bertrand et al.[84] A 20-μL portion of a standard solution or a sample extract in ethyl acetate is put into a 0.5-mL Reacti-Vial pretreated with dichlorodimethylsilane for reproducibility. Then 60 μL of CEDMSDEA reagent and 45 μL of ethyl acetate are added. The solution is shaken briefly and within 5 min, 1 μL of the extract is injected into the gas chromatograph.

Suitable GC conditions[81] are as follows. Instrument: GC/NPD or GC/MS. Capillary column: 15 m × 0.23 mm ID DB-1 (SE-30) capillary column. Carrier gas is helium and the injector is used with an initial split ratio of 32 : 1. The oven temperature is programmed from 180 °C to 208 °C at 3 °C min^{-1} followed by 10 °C min^{-1} to 250 °C. Injection port, detector (NPD) and source (MS) temperatures are set to 275 °C, 300 °C and 220 °C, respectively. When using NPD detection, helium is used as make-up gas at a flow of 30 mL min^{-1} and the flow rates of hydrogen and air at the detector are 2.6 and 100 mL min^{-1}, respectively.

Silylation with N-*(*tert-*Butyldimethylsilyl)*-N-*methyltrifluoroacetamide.* This derivatization procedure is according to Heberer and Stan.[83] An aliquot of a standard solution or sample extract (about 1 mL) is dried under a gentle stream of nitrogen in a sample vial. The residue is dissolved in 50 μL of acetonitrile, then 50 μL of MTBSTFA are added. The derivatization is carried out in sampling vials which are capped with a Teflon®-lined sampler cap and placed in a drying cabinet at 80 °C for 1 h. The mixture is cooled to room temperature and the vials are decapped. The solution containing the derivatives is transferred to 200-μL vial inserts and 1 μL is injected directly in the gas chromatograph.

Suitable GC conditions are as follows. Instrument: GC/MS. Capillary column: 25 m × 0.2 mm ID × 0.33 μm HP-5 capillary column fitted with a 1.5 m × 0.32 mm ID × 0.33 μm HP-5 precolumn. The carrier gas is helium (purity: 99.999%) set to a flow of 28 cm s^{-1} at the initial temperature. The oven temperature is held at 100 °C for 1 min following injection, then programmed at 30 °C min^{-1} to 150 °C, which is held for 1 min, then at 3 °C min^{-1} to 205 °C followed by 10 °C min^{-1} to 260 °C and finally held for 23 min. Injection port and interface temperatures are set to 230 °C and 250 °C, respectively. Samples are injected using hot splitless injection with the split closed for 0.9 min.

3.1.2 Gas Chromatography with Electron Capture Detection

GC with ECD has been used successfully for many years, especially, in trace level analysis of chlorinated pesticides. Analysis by GC/ECD still belongs to the most sensitive detection methods and is the yardstick for other analytical instruments. Many acidic pesticides are substituted with hetero atoms, mostly chlorine, which make them suitable for ECD. Thus, even the methyl esters can be analyzed by GC/ECD. When using methyl, ethyl or butyl chloroformates for derivatization, it is possible to identify and confirm acidic pesticides using only one GC column as shown in Figure 1. In this case, the shift of the retention times caused by introducing a methyl, ethyl or butyl moiety into the individual molecule is used for analyte identification.

Figure 1 ECD chromatograms of a standard mixture containing 13 acidic pesticides as their (a) methyl, (b) ethyl and (c) butyl esters. One nanogram of each compound has been analyzed. 1, dichlorobenzoic acid; 2, clopyralid **(24)**; 3, dichlorprop **(4)**; 4, 2,4-D **(2)**; 5, triclopyr **(40)**; 6, fenoprop **(5)**; 7, 2,4,5-T **(9)**; 8, 2,4-DB **(3)**; 9, picloram **(33)**; 10, fluazifop **(28)**; 11, haloxyfop **(31)**; 12, flamprop **(27)**; 13, acifluorfen **(20)**. (Reprinted from Butz, Stan, *J. Chromatogr.*, copyright (1993),[53] with permission from Elsevier Science.)

Figure 2 ECD chromatogram of a pentafluorobenzylated standard mixture containing 17 acidic pesticides and the surrogate standard compound 2-(4-chlorophenoxy)butyric acid. A sample of 2.5 ng per compound was injected.

As mentioned before, there is one drawback that all alkyl derivatives have in common; they present some problems in ECD detection of lower chlorinated analytes, e.g. mecoprop **(8)**, MCPA **(6)** or MCPB **(7)**. Alkyl esters of acidic pesticides such as bentazone **(10)** or 2-(1-naphthyl)acetic acid **(32)** are not detected by GC/ECD at all.

Lee et al.[64] compared the relative response factors (RRFs) of methyl, trichloroethyl (TCE), pentafluoropropyl (PFP) and PFB derivatives of 13 acidic herbicides applying GC/ECD detection. The RRFs of the PFB esters were found to be twice as large as those of the corresponding TCE esters and much higher than those of the PFP or even the methyl esters. The RRFs of the MCPA methyl or PFP ester were very low, thus both derivatives were found to be inapplicable to the determination of MCPA and other monochlorinated herbicides by GC/ECD at residues levels.[64] On the other hand, trichloroethanol did not react with bromoxynil **(13)**, and the yield of the 2,3,6-TBA **(39)** TCE ester was poor. Therefore, Lee et al.[64] concluded that the PFB esters were the derivatives best suited to the simultaneous determination of all 13 herbicides at trace levels applying GC/ECD. PFB esters increase the sensitivity of ECD detection tremendously and they allow the determination of acidic pesticides independent of their substitution by chlorine. As an example for multiresidue analysis, Figure 2 shows an ECD chromatogram of a standard mixture of 17 acidic pesticides as their PFB esters, amides and ethers.

A major drawback of the PFB ester procedure is the large number of interfering substances in the extract from the environmental matrix when the extract is analyzed by GC/ECD.[28,64,75] Figure 3 shows the ECD chromatogram of a derivatized extract of a drinking water sample measured without additional cleanup procedures.

Figure 3 ECD chromatogram of a pentafluorobenzylated extract of a groundwater sample spiked with nine phenoxy acid herbicides. All analyte peaks are covered by matrix compounds. (Reproduced from Butz[85] by permission of Wissenschaft & Technik Verlag.)

As described by Lee et al.,[64] the analysis of derivatized sample extracts by GC/ECD often needs time-consuming cleanup procedures using gel permeation chromatography (GPC) and/or silica-gel columns. Therefore, the screening of PFB derivatives using GC/MS or using GC/AED has great advantages compared to conventional GC/ECD methods.

3.1.3 *Gas Chromatography with Mass Spectrometry and Gas Chromatography with Tandem Mass Spectrometry*

The coupling of GC to MS has greatly benefited from the development of fused silica capillary columns and the development of small, relatively inexpensive mass spectrometers as dedicated GC detectors. GC/MS instruments which are easy to use and easy to maintain are now readily available to residue chemists. Thus, specialists in MS are no longer a prerequisite for GC/MS operation. MS is the most sensitive method of molecular analysis yielding information on the molecular weight (MW) as well as the structure of the analytes. When GC and MS are directly combined into one GC/MS system, the capabilities of that system are not merely the sum of the capabilities of these two outstanding analytical methods; the increase in analytical information is exponential. Extreme selectivities can be obtained which are of great importance in screening analysis of target analytes in environmental samples.

Positive identification of pesticide residues in environmental samples (soil or water) at trace level concentrations confronts the analyst with a number of problems. The high sensitivity and selectivity of modern GC/MS instruments enable the detection of the analytes at the parts per billion ($\mu g\,L^{-1}$ or $\mu g\,kg^{-1}$) or even at the parts per trillion or parts per quadrillion ($pg\,L^{-1}$ or $pg\,kg^{-1}$) ($ng\,L^{-1}$ or $ng\,kg^{-1}$) level, depending on the matrix and in particular on the chemical structure of the pesticide.

In the beginning, GC/MS was mostly used for the confirmation of results positively monitored with screening methods using less selective detectors such as ECD or NPD. Nowadays, screening for pesticides in environmental samples with full scanning as well as target compound analysis applying SIM programming is becoming more and more popular for the multiresidue analysis of acidic pesticides. GC/MS analysis is sometimes unavoidable because some analytes which do not contain chlorine, fluorine or bromine atoms, such as the methyl esters of bentazone **(10)** or 2-(1-naphthyl)acetic acid **(32)**, are not even applicable to common GC/ECD analysis and often GC/ECD analysis of environmental samples is heavily disturbed by matrix interferences which mostly do not interfere with GC/MS analysis.

3.1.3.1 Electron Ionization Mass Spectrometry Measurements With most modern instruments, full scan spectra can be obtained at the low nanogram or even at the picogram level. Combined with suitable sample preparation methods, as shown in section 4.1.1, these detection limits are sufficient for the analysis of trace level concentrations of pesticides in water samples at the microgram per liter or even down to the nanogram per liter level. Using GC/MS with SIM programming (see section 3.1.3.2) acidic pesticides can be analyzed at much lower concentrations comparable to ECD detection. A prerequisite for GC/MS analysis is, however, knowledge of the mass spectral properties of the analytes, i.e. knowledge about important peaks (molecular ions and dominant fragments) and their corresponding intensities in the individual mass spectrum. Commercially available mass spectral libraries contain the EI mass spectra of up to 275 000 compounds, for example the WILEY library,[86] and there are some smaller, more specialized libraries which contain mass spectra of pesticides, e.g. the HPPEST or the Pfleger, Maurer, Weber library.[87,88] The MS libraries contain, however, only few mass spectra of pesticide derivatives. In this section, some GC/MS chromatograms of derivatized multicomponent standard mixtures of acidic pesticides are shown. Additionally, mass spectral data have been collected for many acidic pesticide derivatives and important mass spectral features of these derivatives will be discussed.

Methyl Derivatives. Figure 4 shows the GC/MS chromatogram of a standard mixture of 17 acidic pesticides which have been methylated with diazomethane. Even the coeluting derivatives of fluroxypyr **(30)** (mass to charge ratio, m/z 209, 268, 270) and 2,4-DB **(3)** (m/z 59, 101, 262) can be identified and quantified by their characteristic ion traces as demonstrated in Figure 5.

This methylation shifts the MW of the analytes by 14 Da. Many of the methyl derivatives exhibit characteristic ions in their EI mass spectra. Exceptions are given by the mass spectra of the methyl derivatives of MCPB **(7)** and 2,4-DB **(3)** which exhibit only noncharacteristic ions with m/z 59 and 101 at high intensities, whereas the molecular ions are of low intensity not suitable for trace level analysis. Table 2 shows the three most indicative ions in the EI mass spectra of individual pesticide derivatives together with their relative intensities. This information, together with the retention times of the analytes, facilitates creation of time scheduled SIM programs for trace level target compound analysis as shown in section 3.1.3.2.

Pentafluorobenzyl Derivatives. Derivatization with PFBBr shifts the MWs of the acidic pesticides by 180 Da. The typical fragment ion in the EI mass spectra of all PFB derivatives is the resonance-stabilized pentafluorobenzylium ion at m/z 181, which is always accompanied by a smaller fragment ion at m/z 161 resulting from the cleavage of HF. As can be seen from Table 3 the characteristic pentafluorobenzylium ion often appears as a base peak in the mass spectra, especially with phenolic pesticides. It may be used as a ''monitoring ion'' for PFB derivatives in SIM programming (section 3.1.3.2),

Figure 4 TIC (total ion current) chromatogram of a methylated standard mixture containing 17 acidic pesticides and the surrogate standard compound 2-(4-chlorophenoxy)butyric acid.

Figure 5 Indicative ion traces for fluroxypyr-methyl (*m*/*z* 268, 270 and 209) and 2,4-DB-methyl (*m*/*z* 59, 101 and 262) extracted from the TIC chromatogram in Figure 4.

but it is not selective and should not be used for identification and quantification of the pesticides. Most of the acidic pesticides exhibit other characteristic fragments or even high intensity molecular ions,[75] which enable their analysis at trace level concentrations. Table 3 shows a compilation of the three most indicative ions in the EI mass spectra of the individual pesticide derivative together with their relative intensities.

Figure 6 shows the GC/MS chromatograms of a derivatized standard mixture and the derivatized extract of a fortified sewage farm groundwater sample. Both chromatograms were recorded by GC/MS applying SIM programming, as described in detail in section 3.1.3.2. Although the fortified sewage farm groundwater sample contains a bulk of matrix compounds, the sample chromatogram looks as transparent as the standard chromatogram. Thus, the identification and quantitation of all 16 acidic pesticides was possible at a concentration level of only 200 ng L^{-1} by using the indicative ion traces.

Trifluoroethyl Esters. Table 4 shows the three most indicative ions in the EI mass spectra of the TFE (trifluoroethyl) esters of the individual pesticide together with their relative intensities.

tert-*Butyldimethylsilyl Derivatives.* Figure 7 shows the GC/MS chromatogram of a standard mixture of 15 acidic pesticides as their TBDMS derivatives. Derivatization with MTBSTFA shifts the MW of the analytes by 114 Da, except where the analytes are also derivatized a second functional group such as fluroxypyr **(30)** and picloram **(33)** (both +228 Da). The molecular ion is mostly weak or absent, but the EI mass spectra of the TBDMS derivatives exhibit very characteristic $(M\text{-}57)^+$ ions resulting from the cleavage of the *tert*-butyl moiety. This very intense peak also enables the determination of the MW for unknown compounds. Other characteristic mass fragments are $(M\text{-}15)^+$, from the cleavage of a methyl group, $(M\text{-}114)^+$, formed by the cleavage of the TBDMS group and $(M\text{-}101)^+$, resulting from the cleavage of the *tert*-butyl moiety and the additional loss of CO_2. Table 5 shows the three most indicative ions in the EI mass spectra of the individual pesticide derivatives together with their relative intensities.

Table 2 Retention times on an HP-5 capillary column, MWs and MS data of some acidic pesticides as their methyl derivatives

Methyl derivative	MW ($g\,mol^{-1}$)	Retention time (min)	Mass 1 (rel. int.)[a]	Mass 2 (rel. int.)[a]	Mass 3 (rel. int.)[a]
Bromoxynil **(13)**	291	16.05	291 (100)	289 (52)	276 (54)
2-(4-Chlorophenoxy)butyric acid (Surrogate)	228	13.94	128 (100)	130 (34)	228 (47)
Clopyralid **(24)**	205	11.58	147 (100)	174 (31)	205 (16)
2,4-D **(2)**	234	16.05	199 (100)	234 (55)	236 (35)
2,4-DB **(3)**	262	21.32	101 (100)	162 (23)	164 (15)
Dicamba **(25)**	234	13.19	203 (100)	205 (64)	234 (29)
Dichlorprop **(4)**	248	15.50	162 (100)	164 (65)	248 (57)
Fluazifop **(28)**	341	23.27	341 (100)	282 (94)	254 (72)
Fluroxypyr **(30)**	268	21.28	209 (100)	211 (64)	268 (51)
Haloxyfop **(31)**	375	24.38	316 (100)	375 (95)	377 (33)
Ioxynil **(14)**	385	22.06	385 (100)	370 (35)	243 (26)
MCPA **(6)**	214	14.24	141 (100)	214 (94)	216 (32)
MCPB **(7)**	242	20.03	101 (100)	59 (71)	242 (9)
Mecoprop **(8)**	228	13.82	169 (100)	142 (91)	228 (74)
Picloram**(33)**	254	22.55	196 (100)	198 (98)	254 (26)
2,4,5-T **(9)**	268	20.08	233 (100)	235 (58)	268 (49)
Triclopyr **(40)**	269	17.77	210 (100)	212 (98)	269 (35)

[a] Relative intensity of the ions in the full scan EI spectrum of the individual compound (base peak = 100).

3.1.3.2 Selected Ion Monitoring Since GC/MS with full scan often does not provide the sensitivity necessary to meet the maximum tolerances in drinking water or soil, GC/MS in SIM mode is applied to achieve lower detection limits. The increase in sensitivity is caused by the increase of the relative individual scan times (also called dwell times) which are spent detecting only indicative ions of the analytes.

GC/MS with SIM is commonly used for the confirmation of positive results obtained with conventional detectors such as GC/ECD. Following decreasing prices of GC/MS instruments, GC/MS with SIM is already in widespread use for screening analysis of pesticides in water.[27] Multiresidue methods using SIM have gained much importance for trace level analysis of pesticides in environmental samples, especially with acidic pesticides.[27] This may also be a consequence of the necessity to derivatize polar compounds prior to GC. Thus, only a limited number of derivatizable compounds has to be targeted. GC/MS with SIM acquisition is often a prerequisite for environmental trace level analysis because derivatized matrix compounds or by-products of the derivatization procedure often interfere with detection by conventional GC detectors.

Heberer et al.[75] reported a method for the detection of more than 30 acidic pesticides as their PFB esters in a single GC run, applying GC/MS with SIM time window programming. In this method, three indicative ions from the mass spectrum were selected for each analyte and an appropriate retention time window for recording those ions was set.[75] Table 6 shows the resulting SIM program used to produce the MID chromatogram, a summation of all ions in each corresponding time window, as shown in Figure 8. In this case, only 20 pg of each analyte were injected and analyzed by GC/MS with SIM. This amount is equivalent to a concentration of $1\,ng\,L^{-1}$ in water analysis presuming 100% recovery of the analytes and a concentration factor of 10 000 being obtained when using the sample preparation procedure described in section 4.1.1. The identity of the compounds can be easily confirmed by extracting the ion traces of the indicative analyte ions.

In general, SIM programming can be used for the analysis of any compound which is amenable to GC. The only prerequisite for SIM programming is knowledge of the individual GC retention times, the indicative masses and their relative abundances in the mass spectra. All this information, including the indicative ions labeled as mass 1 to 3, is given in Tables 2 to 5 for the different derivatives of acidic pesticides. Using this information and recording a full scan chromatogram with a derivatized standard mixture to determine the retention times, the analyst is able to create a suitable GC/MS SIM program for multicompound trace level analysis. To take full advantage of the increase in detection sensitivity provided by the SIM technique, the indicative ions are only recorded in a time window in which the target compound is expected. The only problem with SIM programming is to find intervals in the chromatogram where switching from one window to the other can be performed without missing any of the target compounds. When creating a SIM method for the analysis of so many compounds in one GC run a compromise has to be found between the wish to have the smallest number of target compounds

Table 3 Retention times on an HP-5 capillary column, MWs and MS data of some acidic pesticides as their PFB derivatives according to Heberer et al.[28,75,76]

Common name	MW ($g\,mol^{-1}$)	Retention time (min)	*m/z* 181 (rel. int.)[a]	Mass 1 (rel. int.)[a]	Mass 2 (rel. int.)[a]	Mass 3 (rel. int.)[a]
Acifluorfen PFB ester	541	42.96	100	345 (77)	511 (16)	541 (10)

Figure 8 MID chromatogram recorded with GC/MS applying SIM programming of 34 acidic pesticides as their PFB derivatives (20 pg of each compound). For peak identification refer to Table 6. (Reprinted from Heberer et al.,[75] copyright (1994), with permission from AOAC International.)

in each window and the necessity of finding a sufficient gap in the chromatogram to enable window switching.[75] When using uniform dwell times within the individual SIM time windows the relative intensities of the various ions are comparable with the relative abundances in the full scan mass spectra as compiled in Tables 2–5. For analyte identification in environmental analysis, the peak area ratios of the indicative ions should match within ±20% with the relative abundances of the standard compounds.[41]

In trace analysis, the feature of an adjustable selectivity, as is possible using GC/MS with SIM acquisition, is very valuable and is not provided by a less selective detector such as an ECD.[75] This feature is shown in Figure 9 with the chromatogram of a pentafluorobenzylated derivatization blank. The MID chromatogram of the indicative ions (top) shows a flat baseline with only one small peak in the entire chromatogram, whereas the ion trace of the pentfluorobenzylium ion (*m*/*z* 181) which appears in the mass spectra of all derivatized compounds (analytes and matrix as well) shows strong interference. These peaks represent impurities from the reagents and by-products formed during derivatization. Thus, this ion should not be included in trace level analysis of target analytes. It may, however, be additionally recorded and used as a ''monitor ion'' to obtain an overview of the matrix content or it might help to avoid missing another important peak from a derivatized nontarget analyte.

3.1.3.3 Negative Chemical Ionization Negative chemical ionization (NCI) has been successfully used in environmental analysis for the selective and sensitive detection of electron capturing analytes such as organochlorine pesticides, polychlorinated biphenyls (PCBs) and dioxins.[89,90] Applying GC/MS with NCI appears to be especially promising for the analysis of PFB esters of acidic pesticides. Meiring et al.[73] described the analysis of 10 acidic pesticides as their PFB esters by applying GC with high resolution (HR) NCI/MS and SIM. Lee et al.[64] used GC/MS applying EI and NCI in water analysis to confirm 14 acidic herbicides as their PFB derivatives, and Vink and van der Poll[78] used NCI/MS to confirm eight acidic herbicides after GC/ECD analysis. Stan et al.[91] analyzed more than 30 PFB esters of acidic herbicides applying electron capture NCI using ammonia as reagent gas.

NCI is a so-called ''soft ionization'' technique which in most cases produces intensive molecular anions and shows only little fragmentation. This ionization behavior has some advantages because the molecular anions often

Figure 9 Derivatization blank of the pentafluorobenzylation. (a) MID chromatogram of the indicative ions. (b) Ion trace of *m*/*z* 181. (Reprinted from Heberer et al.,[75] copyright (1994), with permission from AOAC International.)

have an excellent signal-to-noise ratio. On the other hand, low fragmentation may become a problem in trace level analysis because there are no suitable confirmational ions. However, many of the acidic pesticides are substituted by chlorine atoms and therefore show the characteristic chlorine cluster ions, which may also be used to confirm the individual compound.

In the case of the PFB esters, the molecular anions are missing in the NCI mass spectra because the PFB moiety easily cleaves from the molecule during the dissociative electron capture process.[73,91] Thus, the base peaks in the mass spectra are formed by the anions of the original acidic pesticides $(M\text{-}181)^-$.[73,91] Table 7 shows the prominent anions in the ammonia NCI mass spectra of the PFB esters for more than 30 acidic herbicides.

When measuring standard compound solutions, GC/NCI/MS was found to be on average ten times more sensitive than conventional GC/EI/MS. In full scan mode, detection limits between 10 and 100 pg per compound injected were determined.[91] In SIM mode, mecoprop PFB ester could be detected down to 500 fg. For all compounds compiled in Table 7, the detection limits in SIM mode were estimated to be between 0.5 and 5 pg injected.[91]

Unfortunately, these results could not be confirmed when measuring real water samples. The detection limits of GC/NCI/MS with SIM were found to be more than ten times higher than those determined with GC/EI/MS with SIM.[91] In full scan mode the detection limit was on average 100 ng L^{-1}, which is similar to or slightly better than that of full scan mode applying EI/MS. However, in

[b] Rearrangement reactions result in the mono methyl PFB ester.

contrast to EI/MS with SIM, no significant improvement of the detection limits was observed for NCI/MS with SIM.[91] The reason for this phenomenon lies in the selection of suitable anions for SIM programming. The masses of the prominent NCI anions of the PFB esters are much lower than those of the EI ions. Unfortunately, in environmental sample extracts the mass spectral background between m/z 200 and m/z 340 was found to be rather high in NCI/MS.[91] The effective signal-to-noise ratio of the SIM anions was therefore much worse than that observed for the EI/SIM ions of the PFB esters. Thus, Lee et al.[64] recommended extensive cleanup procedures in sample preparation and Meiring et al.[73] recommended the use of GC with HR NCI/MS for low-level analysis of dirty samples after derivatization with PFBBr. Owing to its selectivity HR/NCI/MS is not disturbed by coeluting matrix compounds. However, HR/MS instruments are rather expensive and need well-trained personnel. These instruments are therefore unlikely to be used for routine analysis of environmental samples. Another less expensive alternative is probably provided by low resolution NCI/MS/MS detection using ion-trap MS instruments. This technique has, however, not yet been described for the analysis of acidic pesticides.

3.1.3.4 Tandem Mass Spectrometry Measurements

Another promising analytical approach for the sensitive and highly selective determination of acidic pesticides in environmental samples is the application of GC with MS/MS. For a long time, MS/MS was only possible using highly sophisticated, very expensive MS instruments such as triple stage quadrupole mass spectrometers. Today, MS/MS recording is, with a few restrictions, also applicable using relatively inexpensive ion trap mass spectrometers.

In MS/MS acquisition a ''parent ion'' from the original mass spectrum is selected and fragmented again by collision induced dissociation (CID) forming a daughter ion spectrum. When a suitable parent ion for the individual analyte is selected, the resulting daughter ion spectra are highly selective and unlikely to be disturbed by interfering compounds. The daughter ions mostly exhibit better signal-to-noise ratios, further enhancing the sensitivity of GC/MS analysis. In SRM mode only one or a few daughter ions are monitored for the individual compound. Thus, SRM gives maximum sensitivity and selectivity and, similar to SIM, a time-scheduled SRM programming for multiresidue analysis may be developed. The hardware and operation of MS/MS acquisition are described in more detail elsewhere.[24,25]

MS/MS is already used in routine analysis to confirm positive analytical results and a few laboratories also make attempts to use MS/MS programming for multiresidue analysis of acidic pesticides using GC with ion trap MS. Such methods have not yet been validated over a longer time period in routine analysis, nor have they been published.

3.1.4 Other Detection Methods

3.1.4.1 Gas Chromatography with Nitrogen–Phosphorous Detection GC/NPD is frequently applied in environmental analysis to the determination of nitrogen or phosphorus containing pesticides such as triazine herbicides or organophosphorous insecticides. However, the use of GC/NPD for the determination of acidic pesticides has only been described by Bertrand et al.[81,82] Acidic

Figure 10 NPD chromatogram of a mixture of acidic herbicides derivatized with CEDMSDEA. Compounds: 1, mecoprop **(8)**; 2, dicamba **(25)**; 3, MCPA **(6)**; 4, 2,3,6-TBA **(39)**; 5, dichlorprop **(4)**; 6, 2,6-D; 7, 2,4-D **(2)**; 8, 2,5-D; 9, 2-(1-naphthyl)acetic acid **(32)**; 10, 2,3-D; 11, 3,4-D; 12, (4,6-dichloro-2-methylphenoxy) acetic acid; 13, fenoprop **(5)**; 14, chloramben **(22)**; 15, 2,4,5-T **(9)**; 16, MCPB **(7)**; 17, benazolin **(21)** and 18, 2,4-DB **(3)**. (Reprinted with permission from Bertrand et al., *Anal. Chem.*,[81] copyright (1987), by American Chemical Society.)

pesticides are originally unsuitable for NPD analysis, but derivatization with CEDMSDEA (see section on Silylation with (2-cyanoethyl)dimethyl(diethylamino)silane) introduces nitrogen into the molecules which renders the derivatives suitable for NPD analysis. Figure 10 shows the resulting GC/NPD chromatogram of a derivatized standard mixture.

3.1.4.2 Gas Chromatography with Atomic Emission Detection AED is a highly sophisticated and still very expensive technique which provides high element specific detection of all compounds amenable to GC. In theory, a GC/AED can detect any element in the periodic table except for helium.[92] Unlike the ECD, the AED can also distinguish between fluorine, chlorine, bromine, and iodine. As most modern pesticides contain hetero atoms such as sulfur, phosphorus, nitrogen, chlorine, bromine or fluorine, GC/AED is most suitable for pesticide analysis. However, for practical reasons, it is not always possible to determine all the element traces in one single GC run. Thus, carbon, hydrogen, chlorine, and bromine may be detected in a single GC run or alternatively carbon, nitrogen and sulfur can be monitored simultaneously.[92] Since molecules are fragmented into their constituting elements, these can be quantified individually by external calibration. Thus it is possible to estimate the sum formula of an unknown compound.[92] Several excellent reviews have been written which describe the hardware, the techniques, some applications and limitations of the AED.[92–98]

A major drawback of the AED in trace level analysis is the lack of sensitivity, especially for the important nitrogen or oxygen traces.[93] This drawback may be overcome by using large volume injection techniques such as PTV. Stan and Linkerhägner[93] demonstrated the analysis of 22 acidic compounds including 19 pesticides as their PFB esters at trace level concentrations applying GC/AED. Table 8 compiles the retention times, molecular formulae and detection limits in water analysis for the individual element traces applying GC/AED with PTV injection of 12.5 µL of a derivatized sample extract. The samples (1 L each) have been prepared according to the procedure described in section 4.1.1, therefore the amount injected using PTV corresponds to an aliquot of 125 mL of a water sample. Figure 11 shows a set of element-specific chromatograms obtained for a derivatized standard solution containing the analytes. All analytes are detected with the element traces reflecting their elemental composition. The element traces

Table 8 Compilation of retention times, elemental formulae and LODs in the individual element hetero atom traces of some PFB derivatives of acid herbicides according to Stan and Linkerhägner[93]

[a] LOD (limit of detection) of the multiresidue methods using SPE with RP-C18 (reversed-phase octadecyl) adsorbent as described in section 4.1.1.

Figure 11 GC/AED chromatogram of the hetero element traces of an acidic herbicide standard mixture (1 ng µL^{-1}) derivatized with PFBBr; 12.5-µL cold split PTV-injection with solvent venting. Peak numbering as given in Table 8. (Reproduced from Linkerhägner[98] by permission of Shaker Verlag.)

of chlorine, bromine and sulfur show the AED to be much more sensitive to these than to nitrogen, oxygen or fluorine.[93] Thus the AED seems to be well suited to trace level analysis of compounds containing these hetero atoms, including most acidic pesticides. Other compounds such as 2-(1-naphthyl)acetic acid **(32)** are much more difficult to analyze as can also be seen in Figure 11. Here, 2-(1-naphthyl)acetic acid PFB-ester (peak no. 11) can only be detected in the oxygen or fluorine trace, both of which are heavily disturbed by matrix peaks when analyzing pentafluorobenzylated extracts of real water samples.

3.2 High-performance Liquid Chromatography

HPLC is well suited to the direct and nondestructive analysis of contaminants which are originally not amenable to GC analysis such as thermally unstable and highly polar pesticides or conjugated metabolites.[33] HPLC analysis does not require any preliminary derivatization steps for the separation of acidic pesticides, and pesticide metabolites can often easily be included in the analytical method,[99] see section 3.2.1. HPLC indeed appears to be the most appropriate technique for the determination of these analytes. HPLC is, however, less useful for screening purposes in multiresidue analysis than GC, mainly because of its relatively low separation efficiency.[73] Matrix compounds such as humic acids often interfere because they co-elute with the polar analytes.[100]

In the past, a major drawback of HPLC was the difficulty in coupling LC (liquid chromatography) to sensitive and selective detectors. Progress in coupling LC to MS has improved the possibilities of identification and confirmation of analytes at trace level concentrations.[33] Some applications of HPLC to the analysis of acidic pesticides will be described in the following sections.

3.2.1 Conventional Detection Methods (High-performance Liquid Chromatography with Ultraviolet, Diode Array Detection, Fluorescence Detection and Electrochemical Detection)

HPLC with conventional ultraviolet (UV) or diode array detection (DAD) is one of the most frequently applied methods for the analysis of acidic pesticides in water samples.[56,101–115] Additionally, fluorescence detection (FLD)[106,110,116,117] and electrochemical detection (ELCD)[106] have been used to lower the detection limits of HPLC analysis. Figure 12 shows the separation of a standard mixture of acidic pesticides, including bentazone **(10)** and two of its hydroxylized metabolites using HPLC with DAD.

A major drawback of using UV detection or DAD is that both are often prone to matrix interferences.

Figure 12 HPLC/DAD chromatogram of a standard mixture containing acidic herbicides and 6- and 8-hydroxy-bentazone. (Reproduced from Schuster and Gratzfeld-Hüsgen[118] by permission of Hewlett Packard.)

Figure 13 Typical HPLC/UV chromatogram of an extract of a surface water sample. The peaks correspond to solute concentrations up to the micrograms per liter level. (Reproduced from Noij and Brandt[100] by permission of Springer-Verlag (1995).)

At wavelengths below 300 nm a huge background level from humic substances and other naturally occurring dissolved organic compounds hampers trace analysis of polar analytes.[100] Figure 13 shows a typical HPLC chromatogram of a water sample where the early eluting polar analytes are completely masked by equally polar humic substances. Additionally, in HPLC analysis with UV detection, there is a tremendous risk of false positive results because peak identification is virtually based only on retention times.[100] This latter statement also applies to HPLC analysis using DAD spectra, because these often suffer from interference at lower wavelengths. In

general, the information content of DAD spectra is not comparable to MS spectra. In conclusion, HPLC with UV or DAD detection often does not provide the sensitivity and the degree of confidence which is absolutely necessary in acidic pesticide monitoring.

3.2.2 High-performance Liquid Chromatography with Mass Spectrometry and Tandem Mass Spectrometry

A variety of HPLC/MS techniques using thermospray (TSP) and particle beam (PB) interfaces have been examined in order to develop a rugged system with the necessary sensitivity and selectivity for trace level analysis of acidic pesticides in the environment.[110,119–123] However, it was found that the behavior and sensitivity of these techniques may vary considerably depending not only on chemical and physical properties of the individual pesticide, but also on instrumental and analytical conditions.[73] Another major limitation of LC/MS methods such as TSP/MS using CI processes is the lack of information for MS confirmation. Thus, Geerdink et al.[122] used TSP MS/MS applying the SRM mode to overcome this problem and to lower detection limits. PB interfaces allow both chemical and electron ionization. As discussed in the GC section, EI mass spectra often contain many fragments which are suitable for analyte confirmation purposes. A major drawback of PB interfaces is, however, the lack of sensitivity, which has been overcome to a certain degree using specially designed micro HPLC/PB/MS instruments.[123] Figure 14 shows the total ion PB/MS chromatogram recorded with EI for a standard and a soil sample spiked with acidic pesticides at a concentration of 33.3 ppm. It should be noted that both ionization techniques (PB- and TSP/MS) require much experience, method validation and time for instrument maintenance.

Newer LC/MS interface types, especially API interfaces increased sensitivity and made instrument maintenance and analysis much easier. API is a term covering two different principles of ionization, electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI). ESI is a soft ionization technique which typically generates only ionized molecular ions $[M + H]^+$ (in positive mode) and $[M - H]^-$ (in negative mode). The latest developments, fundamentals, instrumentation and applications of ESI/MS have been described in a monograph by Cole.[124] The first applications of ESI- and APCI-interfaces for the analysis of acidic pesticides applying HPLC/MS with time-scheduled SIM have been described.[125–129] Figure 15 shows a TIC chromatogram recorded with HPLC/ESI/MS of a river water sample spiked with a mixture of acidic pesticides. In Figure 16 the selected ion current chromatograms for selected

Figure 14 TIC chromatogram recorded with HPLC/PB/EI/MS showing (a) the separation of nine acidic herbicides, chlorophenoxy acid standards (125 ppm injected) and (b) the extract of a soil sample spiked at 33.3 ppm with eight phenoxy acid herbicides. ions extracted from the chromatogram in Figure 15 are shown.

Aguilar et al.[129] compared the performance of PB and APCI interfaces for the analysis of several pesticides including some acidic pesticides and concluded that HPLC/APCI/MS is much more sensitive than HPLC/PB/MS.

However, the HPLC/MS instruments are still much more expensive than conventional GC/MS instruments and simple LC/MS is often not sufficient for totally reliable identification of the analytes using low resolution MS. Thus, the use of hyphenated and expensive LC/MS/MS instruments is recommended[130] but not reasonable in routine analysis as long as cheaper alternatives are available.

3.3 Other Techniques

3.3.1 Capillary Zone Electrophoresis

Several of the phenoxy acid herbicides are chiral, e.g. those with the phenoxy substituent on the 2-position of propionic acid, and therefore exist as a pair (racemic

Figure 15 TIC chromatogram recorded with HPLC/ESI/MS of an extract of a river water sample fortified with acidic herbicides at a concentration of 0.5 μg L^{-1}: 1, dicamba **(25)**; 2, bentazone **(10)**; 3, 2,4-dinitrophenol; 4, benazolin **(21)**; 5, coumafuryl; 6, bromoxynil **(13)**; 7, DNOC **(16)**; 8, warfarin; 9, MCPA **(6)**; 10, 2,4-D **(2)**; 11, ioxynil **(14)**; 12, mecoprop **(8)**; 13, dichlorprop **(4)**; 14, 2,4,5-T **(9)**; 15, MCPB **(7)**; 16, 2,4-DB **(3)**; 17, dinoseb **(15)**; 18, fenoprop **(5)**; 19, dinoterb; 20, PCP. (Reprinted with permission from Crescenzi et al., *Anal. Chem.*,[125] copyright (1995), by American Chemical Society.)

mixture) of optical isomers called enantiomers.[131] It has been recognized that only the *R* enantiomers show herbicidal activity and since the 1980s enantiopure products have been developed, registered and now replace the earlier used racemic mixtures in many countries.[50] On the other hand, it has been shown that enantiomeric selectivity is also involved in biotic pesticide degradation processes.[50,79,131] Using high-performance capillary electrophoresis (HPCE) or CE it is possible to distinguish between the different enantiomers of phenoxy acid herbicides. Figure 17 shows the electropherograms of the enantiomeric separation of some acidic herbicides.

Garrison et al.[131] called the phenoxy acids "excellent candidates" for separation by CE, because their pK_a values allow separation by the simplest form of CE called capillary zone electrophoresis (CZE) which separates only charged species. However, enantioselective separation of different acidic pesticide derivatives has also been described applying HR GC/MS[50,56,79] and the enantiomers of mecoprop **(8)** and dichlorprop **(4)** have also been separated by HPLC using columns with chiral solid phases.[56,132]

Several applications of CE for the analysis of acidic herbicides have been reported.[131,133–141] A major drawback of CE analysis is, however, the insufficient sensitivity of commonly used CE techniques applying only to small sample volumes and UV detection[137] which make them unsuitable for trace level analysis of acidic pesticides in environmental samples. Nielen[134] applied CE with field-amplified injection after SPE for the analysis of phenoxy acid herbicides in water at sub parts per billion levels. Jung and Brumley[137] as well as Mechref and Rassi[139] produced fluorescent derivatives of phenoxy acid herbicides and applied CE with laser-induced fluorescence (LIF) detection for trace level analysis down to 0.2 ppb in water samples. Although the detection limits of these CE methods are still much higher than those of other methods, e.g. GC/MS, CE adds an interesting separation tool to the more conventional chromatographic instrumentation. Furthermore, the coupling of CE to API/MS (MS/MS) is a new and promising approach for the trace level analysis of acidic pesticides. Compared to UV detection, MS/MS detection is not impaired by matrix interferences and will also enhance the level of confidence in analyte identification.

3.3.2 Automated Multiple Development Thin-layer Chromatography

AMDTLC is a modern variation of classical TLC which offers much higher separation power than conventional TLC methods. In several reviewing articles the principles, hardware and some applications of AMDTLC in environmental analysis have been described.[142–144] Conventional TLC is not sufficient to separate pesticides from complex matrix compounds as found in environmental samples.[142] AMDTLC instruments are fully automated to process several chromatographic runs consecutively. Drying steps are included between the different TLC runs to remove the mobile phases of the previous runs from the TLC chamber and plate. Thus, it is possible to change the solvents from one run to the other slowly to produce a solvent gradient comparable to HPLC, but in contrast to HPLC it is also possible to change the conditions dramatically, e.g. from acidic to basic eluents. In AMDTLC, the efficiency of the separation

(Reproduced from Butz[85] by permission of Wissenschaft & Technik Verlag.)

is increased remarkably compared to common isocratic elution because the total distance migrated by the solvent front is in the meter range when all individual TLC runs are summed up.[142] The most important feature of AMDTLC which enhances the separation power of this technique tremendously is the so-called ''focusing effect''. During each run, the lower edge of a chromatographed spot is reached first by the solvent front and it begins to migrate to the upper edge of the spot which cannot move until it is wetted by the solvent. Thus, diffusion of the compound spots is suppressed and the analytes are concentrated in sharp peak bands on the TLC plate. It is a prerequisite that the AMD elution gradient always starts with a polar eluent (e.g. methanol) and ends with a nonpolar eluent (e.g. hexane) when using normal-phase silica gel TLC plates. The developed TLC plates are analyzed using a TLC scanner which allows the recording of UV spectra that can be used for confirmation of the analytes.[143]

Butz and Stan[144] applied AMDTLC for the screening in water of 265 pesticides including some acidic herbicides. For the analysis of acidic pesticides, detection limits between 5 and 15 ng have been reported for this method.[143] Figure 18 shows the AMDTLC chromatogram of a pesticide mixture. Using sample preparation techniques with concentration factors up to 10 000, as will be described in section 4.1.1, it is also possible to meet the EU (European Union) maximum tolerances of 100 ng L^{-1} per pesticide in drinking water.[1]

The AMDTLC technique has, however, some drawbacks:

1. The separation power is not comparable to GC.
2. UV detection is not as sensitive as other detection methods, e.g. GC/ECD, GC/MS or HPLC/MS/MS.
3. UV detection is prone to matrix interferences, e.g. by humic acids (as described in section 3.2.1).
4. UV spectra are not comparable to EI mass spectra with respect to information content or selectivity.
5. In contrast to GC, HPLC or CE columns, TLC plates represent an open chromatographic system which requires special care in handling.
6. AMDTLC equipment is, despite its apparent simplicity, relatively expensive.

A new approach is the on-line coupling of HPLC and AMDTLC[6] which has not yet been applied to acidic pesticides. In combination, the separation power of both techniques can be enhanced remarkably, but some of the drawbacks mentioned, such as problems in analyte detection, remain.

4 ENVIRONMENTAL APPLICATIONS

Environmental analysis always consists of three important steps, namely sample collection and handling, sample preparation and finally instrumental analysis. All these steps are equally important and errors in sample collection cannot be corrected in the laboratory. Thus, proper collection and handling of samples is an essential part of producing meaningful analytical results, especially at

trace level analyte concentrations.[145] As far as sample preparation is concerned, it has two functions in environmental analysis: (1) extraction of the analytes from the sample matrix and (2) enrichment of the analytes to a concentrated extract. All parts of the analytical procedure have to be combined, optimized and validated to achieve good laboratory practice (GLP). Sample preparation procedures which can be combined with any of the above instrumental analytical methods are described in the following sections. Nevertheless, some recommendations will help to enable the trace level determination of the acidic pesticides with the highest possible level of confidence, independent of the sample matrix.

4.1 Analysis of Water Samples

In Europe, the identification and quantitative analysis of acidic pesticides at a concentration level of 100 ng L^{-1} in drinking water for a single compound is required to meet the maximum tolerances set by the European Community's drinking water regulation.[1] In order to determine acidic pesticides at such low tolerance levels, the target compounds have to be extracted and enriched from the water sample with high recovery rates and concentration factors up to 10 000. Åkerblom[146] gave an excellent overview of recent techniques and procedures for the extraction and cleanup of water samples in pesticide analysis.

In the past, several analytical methods were described using conventional LLE with dichloromethane,[47,55,63,64,67,68,106] diethyl ether,[39,62] ethyl acetate[35,119,121] or benzene.[69] Recently, SPE has been gaining much popularity in environmental water analysis. SPE has some striking advantages:

(1) It enables concentration of high sample volumes.
(2) It may also be used for sample cleanup.
(3) It needs only small solvent volumes for analyte elution.
(4) It is less toxic.
(5) A high degree of automation is possible.
(6) It saves labor and time, because some samples can be prepared in parallel.
(7) It is usually less expensive.

A variety of SPE materials are commercially available and have been successfully used for the extraction of acid pesticides. Most publications describe the use of modified silica gels, especially RP-C18 adsorbents.[34,37,40,53,72,74–76,78,102,110,117,120] The use of the polymeric materials Amberlite XAD-4,[61] PLRP-S, PRP-1,[104,108,110,114] ion exchanging adsorbents,[38,57] graphitized carbon black adsorbents[115,125,127,128] or even a combination of Carbopack B/SAX[103] has also been described. The flow chart in Figure 19 gives an overview of possible combinations of sample preparation, derivatization and instrumental analysis which can be applied for the determination of acidic pesticides in water.

At present, SPE using RP-C18 seems to be state of the art for the extraction of acidic pesticides from water samples. Therefore, it will be part of the application example described in the following section.

4.1.1 Sample Preparation

The flow chart in Figure 20 depicts an example of a sample preparation procedure for the determination of acidic pesticides in water. This procedure applies SPE with RP-C18 adsorbent, derivatization with PFBBr and GC/MS applying full scan and/or SIM acquisition for analyte detection. Derivatization with PFBBr is described in detail in the section on Pentafluorobenzylation. GC/MS detection applying SIM is carried out using the parameters described in sections on Pentafluorobenzylation, Pentafluorobenzyl Derivatives and section 3.1.3.2 on SIM.

Sample concentration factors up to 10 000 are possible, but sample volumes should be reduced at higher matrix loads to avoid blocking of the SPE cartridges, especially when analyzing surface or even sewage samples. As discussed in section 3.1.1, the choice of the derivatization procedure, as prerequisite for GC determinations applying GC, depends on individual requirements such as the range of compounds which have to be analyzed, the GC detection method and the detection limits required. The use of GC/MS or GC/MS/MS is not always necessary but is recommended when analyzing environmental samples. In general, SPE can be combined with any instrumental method, but the use of GC/MS (or MS/MS) or HPLC/MS/MS for analyte detection is superior in achieving low detection limits, lower matrix interferences and a higher degree of confidence in the analytical results.

Some key conditions have to be considered in applying SPE to the extraction of acidic pesticides from water samples. Samples need to be acidified to a pH < 2 to obtain the undissociated form of the acidic pesticides, otherwise the acidic analytes will not be retained significantly by the nonpolar reversed-phase adsorbent and recovery rates will be low. Nowadays, a variety of RP-C18 materials is commercially available, nonendcapped materials with lower carbon load and some residual active silanole groups have proven to be best suited for the extraction of acidic pesticides. Other important conditions in sample preparation are the conditioning of the SPE cartridges, the percolation velocity, the drying step and the choice and volume of the elution solvent. Some acidic pesticides are applied as their esters in agricultural use. Most of them are easily hydrolyzed into the active acid form in

Figure 19 Possible analytical instrumentation for the multiresidue analysis of acidic pesticides in water. In bold: principle of the analytical procedure described in section 4.1.1. SDB, styrenedivinylbenzene.

the environment, but to include the parent compounds it may also be necessary to introduce a hydrolytic step such as alkaline hydrolysis before extraction.[146] According to Åkerblom[146] phenoxy acids, ioxynil **(14)**, flamprop **(27)**, and fluroxypyr **(30)** are gently cleaved at pH 12 by standing overnight at ambient temperature.

4.1.2 Recoveries, Limits of Detection and Limits of Quantitation

As compiled in Table 9, most acidic pesticides can be extracted and determined at trace level concentrations down to the low nanograms level from water samples applying SPE and GC/MS detection with SIM.[75,76] Low recoveries were only observed for the indolylalkanoic acids, picloram **(33)** and flurenol **(29)**. Fortunately, apart from picloram the other three compounds have no agricultural importance as pesticides.

Figure 21 shows the MID chromatogram of a drinking water sample extract spiked with a mixture of more than 30 acidic pesticides at a concentration level of only $10\,ng\,L^{-1}$ each. All analytes could be detected unequivocally although this concentration is far below all maximum tolerance levels set for pesticides in drinking water. This example shows that multiresidue analysis of acidic pesticides can meet the European maximum

Figure 20 Flowchart showing a suitable procedure for the trace level analysis of acidic herbicides in water.

tolerance levels of 100 ng L^{-1} in drinking water.[1] In modern pesticide analysis, it is possible to achieve limits of detection (LODs) and also limits of quantitation (LOQs) clearly below 100 ng L^{-1} in many different kinds of matrices such as drinking, ground, surface or even sewage water[75,76] as will be described in section 4.4.

The use of new, more ''polar'' RP-C18 adsorbents further enhanced the recovery rates and accuracy of SPE for acidic pesticides. These adsorbents are so-called nonendcapped materials (e.g. BAKERBOND C-18 Polar Plus or LiChrolut® RP-select B) with lower carbon load and some residual active silanole groups. They have proven to be best suited for the extraction of acidic pesticides. Table 10 shows a comparison between different adsorbents for the extraction of some acidic analytes. An alternative to the commonly used reversed-phase adsorbents are polymeric adsorbents which have gained much importance for the extraction of polar analytes. Pichon et al.[114] achieved high recoveries using polymeric adsorbents for the extraction of acidic pesticides at pH 7. The advantage of an extraction at neutral pH is that the fraction of naturally occurring humic acids

which is not soluble at pH values >2 does not interfere with sample analysis, especially when applying HPLC. Fulvic acids are, however, also soluble at neutral pH, thus cleanup of sample extracts may still be necessary.

4.2 Analysis of Soil Samples

Several analytical methods have been reported for the analysis of acidic pesticides in soil samples.[38,41,49,54,66,77,82,121] In particular, the methods of Lee et al.,[66] Bruns et al.[41] and Heberer and Stan[77] have been developed for trace level analysis with LODs of less than 10 µg kg^{-1} (ppb). Lee et al.[66] described the extraction of ten acidic herbicides from soil samples acidified with H_2SO_4 to a pH < 1. In this method a mixture of acetone and hexane (1 + 1) was used for extraction followed by liquid/liquid partitioning with dichloromethane

Figure 21 MID chromatogram of an extract of a water sample fortified with a mixture of acidic pesticides at 10 ng L^{-1}. Internal standard (2,4-dichlorobenzoic acid) added at a concentration level of 200 ng L^{-1}. For peak identification numbers refer to Table 6. (Reprinted from Heberer et al., copyright (1994),[75] with permission from AOAC International.)

and evaporation to dryness. The analytes were derivatized with PFBBr (see section on Pentafluorobenzylation), the resulting extract was cleaned up by silica gel column fractionation and determined by GC/ECD (see section 3.1.2). In their method for the extraction of acidic herbicides from soil samples, Bruns et al.[41] used a mixture of acetone, distilled water and acetic acid (80 + 19 + 1) and a second extraction with 0.1 N KOH. This was followed by liquid/liquid partitioning with dichloromethane, evaporation, derivatization with diazomethane (see section on Methylation with Diazomethane) and GC/MS detection with SIM (see section on Methyl Derivatives and section 3.1.3.2 on SIM). Bruns et al.[41] found GC/MS detection applying SIM to be indispensable in achieving the necessary reliability of the analytical results for trace level concentrations. Heberer and Stan[77] tried to combine the advantages of both methods and invented SPE for analyte enrichment and sample cleanup as well. The resulting method allowed the analysis of dichlorprop **(4)**, mecoprop **(8)**, clofibric acid and naphthylacetic acid

(32) in soil samples at the low parts per billion level. This method, which will be described here, may also be extended to the analysis of some other acidic pesticides.

4.2.1 Sample Preparation and Cleanup Procedures

The method for the analysis of acidic pesticides applies acidic extraction, SPE, derivatization with PFBBr and GC/MS detection with SIM. An additional cleanup step by GPC was found to be useful to protect the gas chromatographic system from matrix contamination.[77] It was, however, found not to be necessary because of the high selectivity of GC/MS detection with SIM.

4.2.1.1 Sample Extraction A 50-g portion of wet soil is weighed into an Erlenmeyer flask and 200 ng of the surrogate standard (e.g. 2,4-D d_6 or 3,4-D) are added to the sample. Then 120 mL of the extraction solvent acetone–water–acetic acid (80 + 19 + 1; v/v/v) is added and the top of the Erlenmeyer flask is covered with aluminum foil and shaken overnight. After centrifuging the sample at 3000 rpm for 5 min, the supernatant is filtered into a round flask. Then 50 mL of the extraction solvent is added and the sample is re-extracted by ultrasound, centrifugation and filtration of the supernatant into the round flask again. The combined extracts are evaporated to approximately 20 mL by means of a rotary evaporator and approximately 180 mL of distilled water is added to this extract.[77]

4.2.1.2 Solid-phase Extraction SPE is carried out according to the procedure described in section 4.1.1.

4.2.1.3 Derivatization Derivatization is carried out according to the procedure described in the section on Pentafluorobenzylation. The resulting extract is analyzed directly by GC/MS. Alternatively, the dried sample residue is dissolved in 1.5 mL of cyclohexane/ethylacetate (50/50; v/v) and this extract is used for further cleanup by GPC.

4.2.1.4 Gel Permeation Chromatography (Optional) A 1-mL portion of the sample extract is transferred to the GPC column by means of a 1-mL injection loop. The first 20 mL of the GPC eluate (dump volume) is discarded, the fraction between 20 and 38 mL (collect volume) is collected and the GPC column is washed with another 25 mL. The collected fraction is evaporated to dryness by means of a rotary evaporator. Then the remaining residue is dissolved in 100 µL of toluene, transferred into a microvial and directed to GC/MS analysis.[77]

4.2.1.5 Gas Chromatography/Mass Spectrometry Detection GC/MS detection applying SIM is carried out using the parameters described in sections on Pentafluorobenzylation and PFB Derivatives and section 3.1.3.2 on SIM.

4.2.2 Recoveries, Limits of Detection and Limits of Quantitation

The recovery rates, LODs and LOQs of a few acidic analytes including dichlorprop **(4)** and mecoprop **(8)** are compiled in Table 11. The LOQs are all below 1 µg kg^{-1} (ppb) soil for these analytes and the recovery rates were all better than 90% even at the lowest of the spiked concentrations of only 1 ppb.[77] Figure 22 shows the resulting MID chromatogram of a derivatized extract of a soil sample fortified with 1 ppb of each analyte. The method may also be extended for the analysis of some other acidic pesticides.[77]

4.3 Interferences

Common interferences in environmental analysis of polar contaminants often derive from natural compounds such as fatty acids or humic acids which occur in water or soil samples at concentrations much higher than those of the analytes. As a consequence, some analytical methods require extended cleanup procedures for sample extracts.[64] In particular, analysis of matrix prone ground or surface water by HPLC with UV or DAD (section 3.2.1) or GC/ECD (section 3.1.2) may suffer heavy interference. Thus, the use of more selective

Table 11 Retention times, indicative EI/MS ions and detection limits in soil

Figure 22 MID chromatogram recorded with GC/MS applying SIM programming of a derivatized extract derived from a sediment sample fortified with $1\,\mu g\,kg^{-1}$ of each analyte. (Reprinted from Heberer and Stan,[77] copyright (1996), with permission from AOAC International.)

detection methods such as MS, MS/MS or AED is often necessary to produce reliable results. Nevertheless, matrix interferences should also be avoided to protect the chromatographic system.

Although MS detection caused by its selectivity is not as prone to interferences as nonselective detectors, some considerations must be taken into account in method development, especially when applying SIM acquisition. Ions selected for SIM must be intense in the mass spectrum and must be indicative, meaning that all ions prominent in the mass spectrometric background, e.g. column bleed or common environmental contaminants such as phthalates and hydrocarbons, should be avoided. Interferences may occur in the GC chromatogram as discrete compound peaks (e.g. phthalates), in certain segments of the chromatogram or during the whole GC run. A compilation of possible background ions that may interfere in the analysis of the analytes is given in Table 12. Several authors[24,147,148] tabulated ions, or published mass spectra of possible background interferences, e.g. solvents, various column coatings, silicon oils or hydrocarbons. Dependent on individual instrumental conditions, such sources of interference should be taken into account and avoided as far as possible.

Interfering matrix compounds can often be separated from the analytes prior to or during gas chromatographic analysis without introducing special time-consuming cleanup steps. Thus, the application of SPE was found to be more selective in separating the target analytes from matrix compounds than LLE.[75] When using SPE for sample preparation, the choice of a suitable material is probably the first crucial step, other important details have already been discussed in section 4.1. In the past, SPE adsorbents of the same type were found to vary significantly in their ability to retain the analytes. Nowadays, most of the suppliers offer different

BHA, butylated hydroxyanisole; BHT, butylated hydroxytoluene.

adsorbents of the same type which are characterized as endcapped, nonendcapped and/or by different carbon loads (see also section 4.1.1). Sometimes considerable batch to batch variations in recoveries have also been reported with materials from the same supplier.[74] Thus, in routine analysis or whenever larger sample series have to be analyzed it may be favorable to buy larger charges of adsorbents from the same batch to assure constant analytical quality.

When applying PFBBr for the derivatization of the acidic analytes, the use of toluene was found to have some advantages compared to commonly used acetone.[75] The PFB derivatives of the acidic pesticides are easily dissolved in toluene while many coextracted matrix compounds such as humic acids remain underivatized and undissolved.[75] Additionally, GC/MS analysis takes advantage of some properties of the PFB derivatives compared to the widely used methyl esters. By increasing the MWs of the analytes significantly (+180 Da) a better separation from coextracted matrix compounds is achieved which results in longer retention times.[75] By recording ions with higher *m*/*z* values, a better detection selectivity is achieved when using EI/MS.[75] Moreover, on a nonpolar GC-column (e.g. SE-54) molecules containing fluorine, such as the PFB derivatives, elute earlier than other molecules of similar molecular mass but without fluorine substitution.[75]

Varying recoveries are often observed when a large amount of matrix is present in environmental samples, thus demanding better control of the sample preparation procedure. The use of suitable internal and/or surrogate standards is almost essential in environmental analysis of pesticides at trace level concentrations. The internal standard may be used to control the reproducibility of the derivatization and the operation of the gas chromatographic system which is also crucial for SIM programming when working with narrow time windows.[76] The surrogate standard is added before analysis and may be used to control the whole analytical procedure including recovery control.[76] Heberer et al.[76] summarized the requirements for the properties of the surrogate standard as follows: (1) it should not be expected in environmental samples, (2) it should give high recoveries from fortified water samples and (3) it should be structurally similar to the most important target compounds. Thus, a suitable surrogate may be an isomer (e.g. 3,4-D or 2,3-D) or even better an isotopically labeled compound such as 2,4-D d_6.

4.4 Some Practical Applications

A few examples of positive findings of acidic pesticides and related polar contaminants are presented in this section to demonstrate the performance, sensitivity and potentials of multiresidue methods in environmental water analysis. The sensitivity of modern environmental analysis is demonstrated in Figure 23, showing the indicative ion traces (*m*/*z* 162, 414, 416) for dichlorprop PFB ester which were recorded for a derivatized sample extract applying GC/MS with SIM. In this case, dichlorprop **(4)** could be identified at a concentration level of only 0.5 ng L^{-1} in a sewage water sample with a dissolved organic carbon content of about 70 mg L^{-1}.[75] Even this small amount of dichlorprop extracted from one liter of sewage with a high load of organic matrix was identified by retention time and with the peak area ratios of the indicative ions matching the abundances listed in Table 3.

The performance and the potentials of multiresidue analysis of acidic pesticides applying GC/MS detection are demonstrated with the example of a derivatized river water sample shown in Figures 24 to 26.

Figure 23 Ion traces *m*/*z* 416, 416, 162 for dichlorprop **(4)** found at a concentration of only 0.5 ng L^{-1} in a sewage water sample. (Reprinted from Heberer et al.,[75] copyright (1994), with permission from AOAC International.)

Figure 24 TIC chromatogram of a river water sample from the Havel near Berlin recorded with GC/MS in full scan mode (*m*/*z* 50–550). Sample spiked with 200 ng surrogate standard and 400 ng 2,4-dichlorobenzoic acid (ISTD) per liter. *Peaks resulting from matrix compounds overlapping the indicated target and standard compounds. (Reproduced from Heberer et al.[76] by permission of Gordon and Breach Science Publishers.)

Figure 25 MID chromatogram recorded with GC/MS applying SIM programming of the river water sample from Figure 24. Sample with 74% recovery for the surrogate standard, containing 150 ng clofibric acid per liter. (Reproduced from Heberer et al.[76] by permission of Gordon and Breach Science Publishers.)

Figure 26 Ion traces extracted from the MID chromatogram of the river water sample shown in Figure 25. (Reproduced from Heberer et al.[76] by permission of Gordon and Breach Science Publishers.)

Figure 27 MID chromatogram of a derivatized extract of a bank filtrate sample recorded with GC/MS applying SIM. This sample contained 65 ng L^{-1} of *o*,*p*′-DDA and 220 ng L^{-1} of *p*,*p*′-DDA.

In the example shown in Figure 24, a TIC chromatogram of a typical river water sample recorded with GC/MS in full scan is presented, demonstrating how a high load of matrix gives a very complex chromatogram. The analyte clofibric acid labeled as 4-CP as well as the surrogate and the internal standard are overlapped by matrix compounds, although the occurrence of the peaks at the expected retention times already suggests their presence. In Figure 25, the corresponding MID chromatogram of the same river water sample recorded using GC/MS with SIM programming (section 3.1.3.2) is presented. The complex chromatogram resulting from full scan has turned into a clear chromatogram with the analyte peaks dominating. When examining the ion traces, as demonstrated in Figure 26, the signal-to-noise ratio is found to be excellent and the detection of the target compounds is not interfered with by matrix compounds. Thus, the 150-ng L^{-1} concentration of the analyte clofibric acid in the river water sample could be easily quantified. Clofibric acid is a phenoxy acid and a structural isomer of the herbicide mecoprop **(8)**. Clofibric acid is, however, not used as a pesticide. It is the biologically active metabolite of blood lipid regulating pharmaceuticals.[149] It is discharged as a persistent drug residue by sewage treatment effluents into the surface water.[149] This example shows clearly the potential of multiresidue analysis of acidic pesticides as it is also applicable to the analysis of other polar contaminants such as drug residues. The drug clofibric acid and another polar contaminant *N*-(phenylsulfonyl)-sarcosine, also originating from sewage effluents, have been found unexpectedly in groundwater samples from the Berlin area during the monitoring of acidic pesticides![150–152] In 1994, both contaminants were also detected at concentrations of up to 270 ng L^{-1} in Berlin drinking water.[153] The findings for clofibric acid in Berlin initiated many drug monitoring investigations. More than 40 pharmaceuticals have been found up to the microgram per liter level in surface water and a few even in groundwater samples.[154,155]

The last example is that of DDA which was also found during the analysis of other acidic pesticides.[156] The MID chromatogram in Figure 27 shows the detection of *o*,*p*′- and *p*,*p*′-DDA as their PFB esters in an extract of a groundwater sample from a bank filtration area. DDA is the long known polar metabolite of the nonpolar insecticide DDT. Although it was known as one key metabolite in the biological degradation of DDT residues, it was never included in any monitoring program for DDT residues in the aquatic environment.[157] Despite other DDT metabolites such as 2,2-bis(chlorophenyl)-1,1-dichloroethane (DDD), 2,2-bis(chlorophenyl)-1,1-dichloroethylene (DDE) or 2,2-bis(chlorophenyl)-1-chloroethylene (DDMU) it was neglected because it could not be analyzed together with the other nonpolar DDT derivatives. DDA can, however, be analyzed together with other acidic pesticides in one multiresidue method. In recent investigations of Berlin groundwater and surface water samples it was found as the major DDT derivative in the surface water of a DDT Superfund site.[157]

ACKNOWLEDGMENTS

The author thanks Mrs K. Schmidt-Bäumler and Mrs G. Fricke for their practical assistance and Mr B. Hatton for his review.

A review of analytical methods for phenyl and sulfonylurea herbicides is reported. Extraction from environmental samples can be carried out using different techniques like liquid–liquid partition, solid-phase extraction (SPE), microwave-assisted solvent extraction, and so on. Both herbicide classes are analyzed mainly using high-performance liquid chromatography (HPLC) coupled with a mass detector. Quantification limits are around the parts per billion level for many compounds. Multiresidue determination is easy for phenylurea compounds, but for sulfonylureas is limited by the different pK_a values of the compounds.

1 INTRODUCTION

Phenylureas and sulfonylureas are two distinct classes of herbicide developed over different periods.

Phenylureas were developed in the 1960s for use as soil-applied herbicides during the relatively short time interval between sowing the crop and its emergence. During this time the weeds are delicate and shallow-rooted and it is difficult to determine what proportion of a toxic dose of herbicide enters through the roots rather than the shoots.

In most members of the substituted urea herbicides, urea **(1)** is trisubstituted as phenylurea **(2)**. One of the amino groups carries either two methyl groups or one methyl and one methoxy group. The other amino group is substituted with a benzene ring which, in most cases, contains halogen atoms.

Urea **(1)** Phenylurea **(2)**

In Table 1 some of the most common phenylurea herbicides are reported.

Phenylureas are solids with a low vapor pressure (10^{-6}–10^{-8} mm Hg or 10^{-4}–10^{-6} Pa) at room temperature and their aqueous solubility ranges from 4 to 700 mg L^{-1}.

Hassall[1] classified ureas as herbicides that are mainly soil acting against seedling weeds and are inhibitors of photosynthesis. Some of the nonselective, preemergence and postemergence uses of phenylurea herbicides are listed in Table 2.

Urea herbicides in solution or suspension readily enter plant roots but the extent of translocation of different substances varies greatly. Chloroxuron and neburon tend to remain in the root system whereas monolinuron, fluometuron and metobromuron are largely translocated to the leaves. Once within leaves, some tend to stay near the leaf veins whereas others enter the mesophyll. Since movement is apoplastic, it is accelerated by factors that increase the rate of transpiration, including high temperatures, lower moisture and opening of stomata.

The principal mode of action of ureas is by disruption of the light reaction of photosynthesis, particularly by inhibition at one or both ends of photosystem II at the level of electron acceptor Q (quinone).

Sulfonylurea herbicides were developed in the mid-1970s for broad-spectrum weed control of a number of crops at very low use ratios (2–75 g active ingredient ha^{-1}). They have the advantage of good crop selectivity and very low acute and chronic animal toxicity.

The chemical structure of a generic sulfonylurea herbicide **(3)** is shown, while Table 3 reports some of the most common sulfonylurea herbicides.

(3)

Hassall[1] classified sulfonylurea herbicides into those that act either at or before cell division.

The site at which the highly specific action of these herbicides is manifest is acetolactate synthase (ALS). This

Table 1 Phenylurea herbicides. R_1, R_2, R_3 and R_4 are shown in **(2)**

Name	R_1	R_2	R_3	R_4	Chemical name
Chlorotoluron	$-CH_3$	$-CH_3$	CH_3-	Cl–	3-(3-Chloro-*p*-tolyl)-1,1-dimethylurea
Diuron	$-CH_3$	$-CH_3$	Cl–	Cl–	3-(3,4-Dichlorophenyl)-1,1-dimethylurea
Isoproturon	$-CH_3$	$-CH_3$	$(CH_3)_2CH-$	H–	3-(Isopropylphenyl)-1,1-dimethylurea
Linuron	$-CH_3$	$-O-CH_3$	Cl–	Cl–	3-(3,4-Dichlorophenyl)-1-methoxy-1-methylurea
Metobromuron	$-CH_3$	$-O-CH_3$	Br–	H–	3-(4-Bromophenyl)-1-methoxy-1-methylurea
Neburon	$-CH_3$	$-CH_2(CH_3)_3$	Cl–	Cl–	1-Butyl-3-(3,4-dichlorophenyl)-1-methylurea

Table 2 Uses of some urea herbicides

Herbicide	Uses
Diuron	Total weed control on paths and other noncrop situations. Annual weeds in alfalfa, maize, cotton, pineapple, sugar cane, sorghum
Fluometuron	Annual weeds in cotton and sugar cane
Linuron	Annual weeds pre-emergence in potatoes, carrots, sorghum, soybean. Kills corn marigold, pre-emergence of spring cereals. Kills some grasses until 2 inches (5 cm) high, some dicots until 5 inches (12.5 cm) high. Seedling weeds pre-emergence and postemergence of ornamental bulbs, corms
Chlorbromuron	Annual weeds in potatoes, soybean, carrots, parsnips
Chlortoluron	Wild oats, blackgrass, dicot seedlings in some winter cereals
Fenuron	As pellets, for woody plants control in noncrop situations
Metobromuron	Annual grasses, dicot in potatoes
Metoxuron	Blackgrass, annual grasses, mayweed in some winter cereals
Monolinuron	Many seedling weeds in potatoes and postplanting of leeks. Annual grasses and seedling dicots in carrots, onions
Chloroxuron	Annual weeds postharvest in strawberries; seedling weeds in container plants

is the enzyme that catalyzes the first step in the synthesis of the branched-chain amino acids valine, leucine and isoleucine. The inhibition leads to the rapid cessation of plant cell division and growth.

Sulfonylurea herbicides are one of the most important classes of herbicides and their use is widespread owing to their selectivity towards a great variety of crops. A list of the uses and doses of the main sulfonylurea herbicides is reported in Table 4.

Analytical methods have been developed since the urea and sulfonylurea herbicides were first introduced. There are two distinct approaches to the development of an analytical method, namely single and multiresidue analyses. In both procedures the steps for determination are essentially the same, but there are differences in the solvents used for extraction and in the equipment. Differences were also observed in the dependence of the matrix by which the chemical must be extracted. The analysis of the two classes, urea and sulfonylurea herbicides, will be described separately.

2 PHENYLUREA HERBICIDES

Since the introduction of phenylurea herbicides, many analytical methods have been developed for their determination in water, soil and food samples. Initially, a direct gas-liquid chromatographic (GLC) analysis was used by a number of authors. Katz and Strusz[2] report a gas chromatographic (GC) method for separation of several urea herbicides and their metabolites. The main drawback in using residue analytical procedures for the substituted urea herbicides was the long and tedious procedure required for qualitative identification and for quantitative measurements after alkaline hydrolysis to the corresponding aniline and the determination of the aniline either directly or as a halogenated derivative.[3–5] This was necessary because of the ease of thermal decomposition of many phenylurea herbicides. Using the programmed technique, separation of the parent compounds can be accomplished using a 1.2 m × 6.35 mm XE-60 column or under isothermal conditions at 130 °C using a 5% SE-30 liquid phase on Chromosorb® W 60 to 80 mesh solid support. The separation of parent herbicides under these conditions is illustrated in Table 5. With the programmed technique, metobromuron and fluometuron cannot be separated because their retention times are almost identical. However, fenuron, linuron, chlorobromuron and monuron are easily separated while diuron is barely detectable. Neither neburon nor chloroxuron can be determined using the programmed technique. Under isothermal conditions, metobromuron and fluometuron were easily separated, and chloroxuron was easily distinguishable. Monuron, diuron and neburon all had a poor response and were essentially inseparable. The limit of detection (LOD) for the compounds was around 50 ng.

In the direct GC analysis, for good separations and reproducible analyses of such compounds, operational parameters must be rigidly controlled. Unfortunately,

Table 3 Sulfonylurea herbicides. R_1 and R_2 are shown in structure of sulfonylureas **(3)**

Name	Formula	Chemical name
A: Sulfonylureas characterized by an aliphatic group in R_1 and by a pyridinic ring (diazine) in R_2		
Amidosulfuron	 **(4)**	1-(4,6-Dimethoxypyrimidin-2-yl)-3-mesyl(methyl)sulfamoylurea
B: Sulfonylureas characterized by a phenylic ring in R_1 and by a pyridinic ring (diazine) in R_2		
Primisulfuronmethyl	 **(5)**	Methyl 2-[4,6-bis-(difluoromethoxy) pyrimidin-2-yl]carbamoyl sulfamoyl benzoate
C: Sulfonylureas characterized by a phenylic ring in R_1 and by a triazinic symmetric ring (1,3,5 triazine) in R_2		
Chlorsulfuron	 **(6)**	1-(2-Chlorophenylsulfonyl)-3-(4-methoxy-6-methyl-1,3,5-triazin-2-yl) urea
Cinosulfuron	 **(7)**	3-(4,6-Dimethoxy-1,3,5-triazin-2-yl)-1-[2-(2-methoxyethoxy)-phenyl-sulfonyl] urea
Metsulfuronmethyl	 **(8)**	Methyl 2-[3-(4-methoxy-6-methyl-1,3,5-triazin-2-yl)ureidosulfonyl]benzoate
Triasulfuron	 **(9)**	1-[2-(2-Chloroethoxy)phenylsulfonyl]-3-(4-methoxy-6-methyl-1,3,5-triazin-2-yl) urea
Triflusulfuronmethyl	 **(10)**	Methyl 2-[4-dimethylamino-6-(2,2,2-trifluoroethoxy)-1,3,5-triazin-2-yl-carbamoylsulfamoyl]-*m*-toluate

(*continued overleaf*)

Table 3 (*continued*)

Name	Formula	Chemical name
D: Sulfonylurea characterized by a pyridinic ring in R_1 and by a pyrimidinic ring (diazine) in R_2		
Nicosulfuron	 **(11)**	2-(4,6-Dimethoxypyrimidine-2-yl)-carbamoylsulfamoyl-*N*,*N*-dimethylnicotinamide
Rimsulfuron	 **(12)**	*N*-[(4,6-Dimethoxypyrimidin-2-yl) aminocarbonyl]-3-(ethylsulfonyl)-2-pyridine-sulfonamide
E: Sulfonylureas characterized by different chemical structures		
Bensulfuronmethyl	 **(13)**	Methyl 2-[[[[[(4,6-dimethoxypyrimidin-2-yl) amino] carbonyl] amino] sulfonyl] methyl] benzoate
Thifensulfuronmethyl	 **(14)**	Methyl 3-[3-(4-methoxy-6-methyl-1,3,5-triazin-2-yl)ureidosulfonyl] thiophene-2-carboxylate
Tribenuronmethyl	 **(15)**	Methyl 2-[3-(4-methoxy-6-methyl-1,3,5-triazin-2-yl)-*N*-methyl-amino] carbonyl amino sulfonyl benzoate

during sample analysis such a restriction often makes direct determination impossible owing to unavoidable interferences. Direct alkylation of urea herbicides was first used in 1973[6] for sample analysis of urea herbicides. Lawrence and Laver[7] reported a GC method for the quantitative analysis of a number of urea herbicides (fluometuron, fenuron, monuron, linuron, diuron, chlorbromuron and chloroxuron) in selected foods (potatoes, carrots, oranges, peas, corn, pineapple, asparagus and spinach) by GLC after alkylation. The compounds were extracted from the crops with ethanol, which was subsequently partitioned between water and chloroform. The organic extract was evaporated to dryness and alkylated with sodium hydride–methyl iodide. The products were extracted with hexane and directly analyzed by GC using a Coulson conductivity detector in the nitrogen mode and a 2 m × 6 mm OD (outside diameter) coiled glass column packed with 4% SE 30/6% QF1 on Chromosorb® WHP (80–100 mesh). No column cleanup was required for any of the samples down to the 0.01-ppm level. Detection limits were about 0.005 ppm. Recoveries were usually 60–100% depending upon the herbicide.

Lawrence[8] reported a comparison of GLC and HPLC for the analysis of some herbicides in foods. This paper is noteworthy in that it is one of the first to propose detection of a urea herbicide (linuron) in foods as well by HPLC with a UV (ultraviolet) detector. Extraction was performed with acetone; extracts were partitioned into petroleum ether–methylene chloride, and cleaned up on a 2% deactivated Florisil® column

Table 4 Uses and doses of sulfonylurea herbicides

Name	Year	Use	Dose (g ha^{-1})
Chlorsulfuron	1982	wheat, barley	10–15
Metsulfuron	1984	wheat, rice	2–8
Sulfumeturon	1984	total	30–40
Chlorimuron	1985	soybean	8–15
Triasulfuron	1988	wheat	8–15
Thifensulfuron	1989	maize, wheat, soybean	7–12
Bensulfuron	1989	rice	40–60
Tribenuron	1989	wheat	8–30
Ethametsulfuron	1990		15–20
Cinosulfuron	1990	rice	40–60
Primisulfuron	1991	maize	10–30
Rimsulfuron	1992	maize, potato	5–15
Nicosulfuron	1992	maize	15–20
Imazosulfuron	1992	rice	20–40
Pyrazosulfuron	1992	rice	10–40
Amidosulfuron	1992	wheat	15–20
Triflusulfuron	1994	sugar beet	30–40
Flazasulfuron	1994	pasture grasses	20–100
Prosulfuron	1994	maize	10–20
Halosulfuron	1995	maize	18–35
Sulfosulfuron	–	wheat	10–20
Azimsulfuron	1996	rice	20–25
Ethoxysulfuron	–	wheat, rice	15–30
NC-330	–	cereal grains	15–20
DPX-T5975	–	cotton	10–25
Oxasulfuron	–	soybean	60–90
Flupyrsulfuron methyl sodium	–	wheat	10

Table 5 Retention times (minutes) of urea herbicides under programmed and isothermal conditions

Compound	Retention time – programmed (min)	Retention time – isothermal (min)
Fenuron	12.60	5.90
Metobromuron	13.95	15.15
Fluometuron	13.95	7.30
Linuron	16.15	23.65
Chlorobromuron	16.95	26.40
Monuron	17.75	1.00
Diuron	20.30	2.35
Neburon	–	1.55
Chloroxuron	–	20.90

before direct chromatographic analysis. Linuron was tested in cabbage and wheat samples both at 2 ppm and 0.2 ppm, with GLC (electron capture detector (ECD) and electrolytic-conductivity detector) and HPLC with a UV detector. All detectors could detect linuron at 0.2-ppm level. However, for electrolytic-conductivity analysis much larger quantities of samples had to be injected because of the low detector sensitivity for linuron. Electron-capture GLC and HPLC gave similar results.

Farrington et al.[9] reported an HPLC analytical method for the determination of several phenylurea herbicides (chlorbromuron, chlortoluron, chloroxuron, diuron, linuron, metobromuron, monolinuron and monuron) in grain, soil and river water. The herbicides were extracted from grain and soil samples with methanol and from water samples with dichloromethane. Organic extracts were chromatographed on microparticulate silica bonded with octadecyltrichlorosilane using a mixture of methanol, water and ammonia as mobile phase. Recoveries were satisfactory; the lower recoveries from wheat may be attributable to residual oil, which remains after the evaporation of the dichloromethane, increasing the volume of the solvent, as this oil is miscible with methanol. The lower limits of detection were estimated to be 0.2 ppm for wheat and soil and 0.01 ppm for river water. Below these levels both coextractives and signal noise interfere.

Numerous HPLC methods for determining phenylurea herbicides in samples were later reported.[10,11]

Over the years, analytical techniques have improved, especially concerning the sensitivity of the methods, which in the 1980s reached parts per billion and parts per trillion levels.

De Kok et al.[12] described several chromatographic procedures for the determination of 15 phenylurea herbicides and their aniline degradation products. Analysis of the separate classes of compounds was achieved by reverse- and normal-phase HPLC followed by determination by capillary GC with an ECD. The anilines were formed by catalytic hydrolysis of the herbicides on silica columns (impregnated with 1 mmol g^{-1} of dimethylamine) and were derivatized with heptafluorobutyric anhydride for determination by GC with ECD (for nanogram levels of herbicides). A range of 14 heptafluorobutyramides could be separated on CP-Sil 5 fused-silica columns, with detection limits (by ECD) of almost 0.2 pg. These and other techniques can be combined as complete schemes for the analysis of mixtures of the herbicides and the corresponding anilines.

Luchtefeld[13] reported an original method for the simultaneous determination of six phenylurea herbicides (chlorbromuron, chloroxuron, diuron, fluometuron, linuron and metobromuron) in eight different food products (asparagus, carrots, celery, corn, grapes, onions, potatoes, strawberries) by liquid chromatography (LC). The samples were extracted twice with methanol, by homogenizing the sample in the centrifuge bottle, and then centrifuging instead of filtering, so less sample manipulation was involved and solvent evaporation was minimized. The partition step was included to provide some cleanup as well as a means of transferring the residues to methylene chloride for further chromatographic cleanup. A single hexane extraction was sufficient to remove some oils that are found in products such as corn. Column

chromatography was included as a final cleanup prior to LC analysis. The Florisil® column was selected since it revealed no inconsistencies between batches. The extracts were analyzed using LC with postcolumn photodegradation, chemical derivatization with orthophthalaldehyde and spectrofluorometry. The LC procedure using postcolumn photolysis and chemical derivatization proved to be very selective for determining phenylurea herbicides in the presence of some food excipients which remain after partition and column cleanup. When UV detection alone was used, these excipients interfered with the analysis. Gradient elution was used to aid the separation of individual herbicides, to help separate any coextractives from herbicides and to remove coextractives from the column in each assay. Two mobile phase systems were used for the gradients: methanol–water (m-w) and acetonitrile–water (a-w). Recoveries were determined by spiking eight different food products with six phenylureas at 0.05 and 0.5 ppm. Average recovery at 0.05 ppm was 95% ± 7.9 and at 0.5 ppm, was 98% ± 6.9. Table 6 reports the LOD and the LOQ for the six phenylureas. The LOD and LOQ were determined by calculating the amount of phenylurea required to give a response that was three times the baseline noise for LOD and ten times the baseline for LOQ. As indicated by the data in Table 6, the detection and quantification limits were lower for the mobile phase system of acetonitrile and water. The described LC procedure with gradient elution, postcolumn photolysis and chemical derivatization has resulted in an unprecedented selectivity for the analysis of phenylureas.

Kuehne et al.[14] presented an analytical method for the determination of phenylurea herbicides in crops by column-switching HPLC, which allowed an improvement in residue analysis of phenylurea herbicides in terms of sensitivity. The method involves hydrolysis of a sample (5 g) of crops with aqueous NaOH for 6 h under reflux, partition of extract by steam distillation into hexane, partition into methanol–0.2 M HCl (33 : 67) and dilution with a mobile phase. Analysis was by column-switching HPLC on a column of Nucleosil® SA (10 μm), followed by a column of Nucleosil® C (10 μm), with methanol–aqueous phosphate buffer of pH 7 (33 : 67 and 3 : 2, respectively) as mobile phase (1 mL min^{-1}), and detection on the first column at 280 nm and on the second column at a vitreous carbon electrode at 0.9 V. Recoveries were 80–110% and detection limits were 0.02 mg kg^{-1} for each herbicide.

Table 6 LOD and limit of quantitation (LOQ) for the six phenylurea using two mobile phases

Herbicide	LOD (ppm)		LOQ (ppm)	
	m-w	a-w	m-w	a-w
Chlorbromuron	0.006	0.003	0.022	0.011
Chloroxuron	0.002	0.001	0.008	0.003
Diuron	0.002	0.001	0.007	0.003
Fluometuron	0.002	0.001	0.006	0.003
Linuron	0.004	0.005	0.014	0.017
Metobromuron	0.004	0.004	0.015	0.014

Di Corcia and Marchetti[15] presented a rapid and sensitive method for the determination of phenylurea herbicides in environmental aqueous samples by extraction with a Carbopack® cartridge followed by HPLC. The water sample is preconcentrated by passage at a flow rate of 150 mL min^{-1} through a 250-mg graphitized carbon black (Carbopack® B) cartridge. After washing with 0.6 mL of methanol, the Carbopack® B trap is connected to a cartridge containing a strong cation exchanger. Organic matter trapped by the Carbopack® cartridge was eluted by passage of 6 mL of methylene chloride–methanol (95 : 5, v/v). Anilines and other basic compounds which can complicate the analysis of phenylureas were readsorbed on the exchanger from the methylene chloride–methanol mixture flowing through it, while the phenylureas passed through completely unretained. After evaporation and redissolution, the sample is subjected to reversed-phase gradient elution HPLC with a 25 cm × 4.6 mm ID (internal diameter) column filled with 5-μm LC-18 reversed-phase packing. The organic modifier was methanol–acetonitrile (85 : 15, v/v). Gradient elution of phenylureas was performed by linearly increasing the percentage of organic modifier from 47–70% in 20 min. It was shown that, in order to fractionate the 14 phenylureas considered, 15% acetonitrile in methanol gave the best results. Phenylureas were detected with the UV detector set at 250 nm. Recoveries of the phenylureas added to water at levels between 30 and 300 ng L^{-1} were always over 92%. LOD (signal-to-noise ratio = 3) was estimated to be about 1 ng L^{-1} for a 2-L sample. One of the advantages of the liquid–solid extraction (LSE) over liquid–liquid partitioning is that sampling and extraction of a water sample can be done simultaneously by passing the water through a sorbent trap as it is pumped at the sampling site. The small volume cartridge can then be transported to the laboratory for desorption and HPLC analysis.

Hatrik and Tekel[16] reported a review of the methods for the determination of phenylurea herbicides, among other pesticide classes, in water samples.

The introduction in the 1990s of new accessories for the classic HPLC (diode array detectors, microcolumns) has led to new efforts in the development of original analytical methods for the determination of phenylurea herbicides in samples.

Brandsteterova et al.[17] described a method for the determination of linuron and monolinuron in milk samples using micro-HPLC. Milk (50 mL) spiked with linuron and monolinuron at 0.01–1 mg kg^{-1}, was mixed

with 50 mL of methanol and 10 mL of 0.1 M sodium acetate. After cooling in ice water for 10–15 min, the precipitate was filtered off and this process was repeated. The combined filtrates were extracted with $CHCl_3$ (3×30 mL) and the combined extracts were dried over Na_2SO_4 and concentrated to 2 mL at 40 °C. The residue was applied to a cartridge containing 3 g of Florisil® topped with 1 g of Na_2SO_4; elution was performed with 10 mL of $CHCl_3$. The eluate was evaporated to dryness and the residue was dissolved in 500 µL of methanol. The solution was filtered and the filtrate was analyzed by HPLC on a column (25 cm × 1 mm) of LiChrosorb® RP-18 (5 µm) with a mobile phase (60 µL min^{-1}) of aqueous 70% methanol and detection at 245 nm. Recoveries were 78.6–91.3% for linuron and 74.9–86.2% for monolinuron: the corresponding coefficients of variation were 0.8–1.8% and 0.7–1.2%.

Boussenadji et al.[18] reported a method for the determination of phenylureas in water using microcolumn HPLC. Water (1 L) was mixed with 10 mL of 0.1 M sodium acetate, filtered and extracted with CH_2Cl_2 or $CHCl_3$ (3×50 mL). The combined extracts were dried using anhydrous Na_2SO_4 and evaporated to dryness at 40 °C. The residue was dissolved in 100 µL of methanol and a 0.2 µL portion of the solution was analyzed by HPLC on a column (30 cm × 1 mm) of Kromasil® C18 (100 Å; 5 µm) with a mobile phase (20–40 µL min^{-1}) of water–methanol (3 : 1, v/v) in 0.01 M $LiClO_4$ adjusted to pH 5.5 using 1% H_3PO_4, UV detection at 254 nm and electrochemical detection at 1.35 V vs Ag–AgCl. Under these conditions, UV detection was more sensitive for linuron, whereas electrochemical detection exhibited a higher sensitivity for metoxuron, diuron and neburon. The detection limit for each herbicide was 0.05 ng.

Lagana et al.[19] reported a method for multiresidue analysis of phenylurea herbicides in crops by HPLC with diode array detector. Crops (20 g) were chopped and blended with 80 mL of methanol. The mixture was filtered and the filtrate was diluted to 100 mL with methanol. A 5-mL portion was passed through a LC-18 cartridge (6 cm × 8 mm) and the cartridge was washed with 5 mL of aqueous 80% methanol. This solution was diluted with 40 mL of H_2O and applied to a Carbopack® B cartridge (6 cm × 12 mm). The phenylureas were eluted with 6 mL of methanol–dichloromethane (1 : 19, v/v) and the eluate was evaporated under N_2 at 40 °C. The residue was dissolved in 250 µL of aqueous 40% methanol and a 50-µL portion was analyzed on a column (25 cm × 4.6 mm) of C1 (5 µm) equipped with a guard column (2 cm × 4.6 mm) of Supelguard® LC-18, with gradient elution (1.5 mL min^{-1}) with acetonitrile–methanol (3 : 17, v/v) in water and detection at 242 nm. Thirteen herbicides were separated using this approach. Recoveries of 0.05–0.2 ppm of each, added to nine different crops, ranged from 76 to 100%, with no interference from the matrix. The detection limit was 0.01 ppm. Confirmation of the identity of each phenylurea was obtained from complete spectra with a diode array detector.

The immunoassay technique has also been developed for analysis of phenylureas in environmental samples.

Newsome and Collins[20] presented the development of an ELISA (enzyme-linked immunosorbent assay) for urea herbicides in foods. Four haptens analogous to phenylurea herbicides were coupled to human serum albumin and ovalbumin in order to prepare immunogens and coating proteins, respectively. Antisera raised in rabbits immunized with three of the immunogens bound strongly to microtiter plates coated with a homologous hapten such that competitive assays were developed with the use of heterologous coating proteins. The specificity of the assays to 13 related compounds was studied. The *N*′-(4-chlorophenyl)-*N*-dimethylurea hapten system was used to determine monolinuron, diuron and linuron in foods. Methanol extracts (25 µL) were incubated at 4 °C for 30 min with antiserum diluted 1 : 4000 with bovine serum albumin, and 200-µL portions were added to microtiter plates which were then incubated for a further 15 min. The plate wells were emptied, washed and incubated at room temperature with a 1 : 1000 dilution of goat anti-rabbit IgG conjugate (210 µL). The wells were again emptied and washed, 210 µL of substrate (*O*-phenylenediamine dihydrochloric acid and H_2O_2 in citrate buffer) were added and after 20 min at room temperature, 2.5 M H_2SO_4 was added before optical density measurement at 492 nm. Satisfactory recoveries of monolinuron and diuron were obtained from food fortified at the 40–160 ng g^{-1} and 0.25–2.0 µg g^{-1} levels, respectively.

Schneider et al.[21] described a highly sensitive and rapid ELISA for the phenylurea herbicides diuron, monuron and linuron. Antisera, obtained from rabbits immunized with monuron–BSA conjugates which contained a C3 or C5 methylene group at terminal nitrogen were adsorbed on microtiter plates overnight at 4 °C in 0.5 M carbonate buffer of pH 9.6 and washed. Monuron, diuron and linuron samples (50 µL) and enzyme tracer (horseradish peroxidase–hapten conjugate; 50 µL) diluted in 0.2 M phosphate buffer in 8% saline, supplemented with 0.1% Tween 20 of pH 7.8 were incubated on the antibody-coated plate for 15 min. A 3,3′,5,5′-tetramethylbenzidine substrate solution (100 µL) was added, the reaction stopped after 15 min and absorbances were measured at 450 nm. Analyses were class or compound selective for individual herbicides dependent on the antisera used. Monuron, diuron and linuron demonstrated 50% inhibition values at 0.4, 0.5 and 0.8 µg L^{-1} and detection limits of 0.04, 0.05 and

0.08 μg L^{-1}, respectively, in buffer. The method was applied to the analysis of water, orange juice and milk.

Katmeh et al.[22] described a competitive ELISA for the determination of the phenylurea herbicide chlortoluron in water and biological fluids. Antibodies were raised in sheep against a *N*′-(3-chloro-4-methylphenyl)-*N*-methyl-*N*-carboxypropyl urea/bovine thyroglobulin conjugate and the resulting antiserum was used in an ELISA for chlortoluron in natural and potable water and in plasma and urine. A microtiter plate was coated with 200 μL per well of the chlortoluron antibody diluted 8000-fold with 0.07 M sodium barbitone buffer of pH 9.6. After overnight incubation at 4 °C, 100 μL of the sample and 100 μL horseradish peroxidase-labeled chlortoluron, diluted 16 000-fold in PBS (phosphate buffered saline) containing 2.5% normal sheep serum, were added to each well and the plate was incubated for 1 h at 37 °C. Then, 200 μL chromagen substrate were added to each well. After a further 30-min incubation, the absorbance was measured at 450 nm. The calibration graph was linear up to 100 μg L^{-1} of chlortoluron and the detection limit was 0.015 μg L^{-1}. The intra- and interassay RSDs (relative standard deviations) ($n = 6$) were 2.6–6.8% and 6.9–14.6%, respectively. Recoveries of chlortoluron added to water and biological fluids were 78–127% and 87–113%, respectively.

Guihot et al.[23] reported the application of immunoassays for molinate and diuron herbicides to field water analysis. The two ELISA described can be carried out either on microwell plates in the laboratory or in polystyrene tubes in the field. Both assays are based on competition with a horseradish peroxidase conjugate of the herbicide for immobilized antibodies against the herbicide, although the assay for diuron requires prior coating of the plate or tube with protein A before coating with the antibody. The detection limits of the laboratory and field assays were 0.5 and 1 ppb for molinate and 0.02 and 0.15 ppb for diuron. There were no appreciable cross-reactions in the assays for molinate, but other phenylurea herbicides cross-reacted in the diuron assays.

Other work helps to present a complete overview of all analytical methods for phenylurea herbicides utilized through the 1980s and 1990s.[24–39]

3 SULFONYLUREA HERBICIDES

Owing to their thermal and chemical instability, the determination of sulfonylurea herbicides at low levels is very challenging and many different approaches have been reported. The earliest approaches utilized normal-phase LC with photoconductivity detection, however this detector has unacceptably long equilibration times. Sulfonylureas are not directly amenable to GC because of their extremely low volatility and thermal instability. Nevertheless, GC has been used in conjunction with diazomethane derivatization, pentaflurobenzyl bromide derivatization and hydrolysis followed by analysis of the aryl sulfonamides. These approaches have not been widely accepted, most likely because none of them perform well for the entire family of sulfonylureas, and while capillary electrophoresis has been evaluated for water and soil, the low injection volumes required may not yield the required sensitivity for certain applications. Enzyme immunoassay has been used for chlorsulfuron and triasulfuron, with LODs ranging from 20 to 100 ppt in soil and water. The most common approaches to sulfonylurea determinations currently involve reversed-phase HPLC with either UV or mass spectrometric (MS) detection. HPLC/MS has been used in conjunction with thermospray, fast-atom bombardment and direct liquid introduction. Electrospray and tandem mass spectrometry (MS/MS) have been combined.

The first sulfonylurea herbicide (chlorsulfuron **(6)**, see Table 3) was introduced in 1982 and since then analytical methods for the determination of sulfonylurea herbicides in different matrices have appeared in journals worldwide.

3.1 Environmental Samples

Sulfonylurea analysis of both soil and water samples can be performed using quite different extraction and determination methods.

3.1.1 Extraction Techniques

Several methods have been proposed using liquid extraction for soil and water samples. Both matrices are extracted by modifying the pH of the medium and using different cleanup techniques.

For chlorsulfuron determination in soil, samples were extracted[40] with aqueous 0.1 M Na_2CO_3–0.1 M $NaHCO_3$ (pH 10). The aqueous solution was washed three times with chloroform. Because the pK_a of chlorsulfuron is about 3.8 the compound remained in the aqueous solution in its anionic form. The chloroform layers were then discarded. The pH of the aqueous solution was adjusted to 3–4 by adding 10% HCl and the solution was extracted three times with toluene and evaporated to dryness by adding 1% glacial acetic acid. The residue was dissolved in the mobile phase and purified in a silica Sep-PAK®.

Soil samples were extracted[41] for nicosulfuron **(11)** and rimsulfuron **(12)** (see Table 3) determination by vortex mixing with aqueous 80% acetonitrile (Table 7). The extract was filtered and the filtrates were concentrated to a reduced volume with nitrogen and directly analyzed

Table 7 Recovery results for multiresidue analysis of nicosulfuron, rimriduron and metabolites

Test compound	Fortification (ppm)	% Recovery	% Standard deviation
Nicosulfuron	0.02–0.20	81–96	7–22
n-Metabolite	0.02–0.20	83–97	8–14
Rimsulfuron	0.02–0.20	74–88	7–11
r-Metabolite	0.02–0.20	80–101	8–22

by a LC/MS (liquid chromatography/mass spectrometry) technique.

Tribenuron-methyl **(15)** was extracted[42] from 500-mL filtered sample of water on a C18 SPE column and cleaned up on a silica column. Chlorsulfuron **(6)**, metsulfuron-methyl **(8)** and thifensulfuron-methyl **(14)** (see Table 3) were extracted and cleaned up similarly after pH adjustment of the sample to 4.5 with aqueous 8.5% H_3PO_4. Each extract was evaporated to dryness in a nitrogen stream and the residues were dissolved in 1 mL aqueous 10% acetonitrile. The method could be applied to other water types, e.g. ground, runoff and surface water.

An analytical screening method for the determination of nine sulfonylurea herbicides (see Table 8) in soil and water was reported by Powley and de-Bernard.[43] Fifty grams of soil were extracted with 100 mL of 80 : 20 (v/v) 0.1 M ammonium carbonate–acetone solution while 200 mL of water sample was directly extracted as indicated below. Soil extract and water samples were passed through a preconditioned 1 g C18 SPE cartridge. The pH of water samples was adjusted to 3.0–3.5 using dilute phosphoric acid. Elution was performed with 10 mL of 0.1% (v/v) glacial acetic acid in ethyl acetate. The eluates were evaporated down and reconstituted in ethyl acetate. After further passage through a 1 g silica SPE cartridge the sample was analyzed by HPLC. This method is not applicable to the determination of nicosulfuron **(11)** and rimsulfuron **(12)** (see Table 3) because these compounds are not quantitatively eluted from the silica cartridge.

Rodriguez and Orescan[44] analyzed 12 different compounds (see Table 9) in water samples using a similar approach. Water (250 mL) was treated with 2.5 mL of acetic acid and drawn through a preconditioned RP-102 SPE cartridge. Elution was performed with 10 mL of methanol and the eluate cleaned up using an anion-exchange cartridge (SAX) stacked on top of an alumina cartridge. The elution was performed with 17 mL of 0.5% acetic acid in dichloromethane with final suction. The final extracts were analyzed using electrospray LC/MS.

In another study[45] nicosulfuron **(11)**, thifensulfuron-methyl **(14)**, metsulfuron-methyl **(8)**, sulfumeturon-methyl, chlorsulfuron **(6)**, bensulfuron-methyl **(13)**, tribenuron-methyl **(15)** (see Table 3) and chlorimuron-methyl recovered from soils were dissolved in 100 µL 90% acetonitrile/5 mM ammonium acetate at pH 3.5 and a 10 µL sample was transferred to a Betasil® C18 (5 µm) column (15 cm × 2 mm ID) with gradient elution (200 µL min^{-1}) with 90% acetonitrile/5 mM ammonium acetate. Chlorsulfuron **(6)**, metsulfuron-methyl **(8)**, thifensulfuron-methyl **(14)** and triasulfuron **(9)**[46] at a concentration of 6 µg kg^{-1} were extracted for 20 min from 20 g of soil using 120 mL of 0.1 M ammonium carbonate at pH 7. After centrifugation for 20 min, the supernatant

Table 9 Recovery results for 12 sulfonylurea herbicides in water. Fortification levels were 0.1–1.0 ppb ($n = 17$)

Test compound	% Recovery	% Standard deviation
Thifensulfuron-methyl	98–104	3–12
Metsulfuron methyl	97–104	3–9

Thifensulfuron-methyl	76–91	1–13	93–104	2–13
Tribenuron-methyl	81–92	6–17	92–101	8–18

was acidified to pH 3–3.5 using dilute H_3PO_4 and applied to a SPE column. The herbicides were eluted with acidic ethyl acetate, dried at 40 °C, reconstituted in methanol, agitated and mixed, evaporated to <0.4 mL and made up to 1 mL with aqueous 5% acetonitrile.

An SPE method based on polymeric sorbents was developed for the extraction of water and soil samples. SPE was performed[47] on cartridges preconditioned with methanol and water. Water samples were adjusted to pH 3.5 with 10% H_3PO_4 before application. Elution was effected with dichloromethane. The eluent was dried over sodium sulfate, evaporated under nitrogen and dissolved in 30% acetonitrile in high-purity water.

Water was acidified[48] to pH 3 ± 0.2 with anhydrous acetic acid, extracted by reversed-phase SPE eluted with methanol and cleaned up on a tandem system comprising a strong-anion exchange SPE cartridge stacked on an alumina SPE cartridge. The sample was eluted with 0.5% methylene acetic acid in dichloromethane, dried under nitrogen at 30 °C and reconstituted with 0.05 M acetic acid. Water (1 L) was acidified to pH 2 with HCl, mixed with 5 mL methanol and subjected to SPE on Empore® C18 disks using ethyl acetate for elution. The eluate was dried over anhydrous sodium sulfate, evaporated to near dryness and reconstituted in ethyl acetate prior to derivatization with diazomethane solution for 30 min. The solvent was removed under nitrogen and the sample dissolved in toluene for GC analysis. Soil (100 g) was extracted with 0.1 M $NaHCO_3$ with sonication and centrifuged. The extract was filtered, adjusted to pH 2 and mixed with 2 mL methanol prior to SPE and analysis as described above, but using a glass fiber filter on top of the extraction disk.

Seven sulfonylurea herbicides,[49] thifensulfuronmethyl **(14)**, metsulfuron-methyl **(8)**, triasulfuron **(9)**, chlorsulfuron **(6)**, rimsulfuron **(12)**, bensulfuronmethyl **(13)** and tribenuron-methyl **(15)** (see Table 3) were isolated from water by off-line SPE on a Carbograph 4 cartridge (0.5 g, 120–400 mesh). Water was forced through the cartridge at 70–100 mL min^{-1}. The cartridge was flushed with 20 mL of water at <10 mL min^{-1}, with air for 1 min, with 2 mL of methanol and with 12 mL of dichloromethane–methanol (4 : 1) at about 8 mL min^{-1}. Herbicides were recovered by backflushing the cartridge with 8 mL of 10 mM acetic acid in dichloromethane–methanol (4 : 1) at 6 mL min^{-1}. The eluate was evaporated to dryness and the residue was dissolved in 200 µL of 2 mM acetic acid in H_2O–acetonitrile (2 : 1) and analyzed by LC.

Cinosulfuron **(7)**, thifensulfuron-methyl **(14)**, metsulfuron-methyl **(8)**, sulfumeturon-methyl and chlorsulfuron **(6)**[50] (see Table 3) were extracted from soil using microwave-assisted solvent extraction. A mixture of 10 g of soil and 20 mL of CH_2Cl_2–methanol (9 : 1) was heated at 60 °C for 10 min in a microwave extraction system operated at 50% power and with a pressure limit of 100 psi (689 500 Pa). The extract was dried over sodium sulfate and a 5 mL volume was evaporated to dryness at 40 °C. The residue was dissolved in 100 µL of acetonitrile and the solution was diluted with 900 µL of water for HPLC analysis.

Supercritical fluid extraction was optimized for the extraction of metsulfuron-methyl **(8)**, sulfumeturon-methyl and nicosulfuron **(11)** (see Table 3) from soils.[51] Quantitative extraction was only achieved after 30 min at a high CO_2 density (0.9 g mL^{-1}) and with a low methanol modifier concentration (2% w/w). Good recoveries of metsulfuron-methyl **(8)** and sulfumeturon-methyl (75–89%) were obtained, but recoveries of nicosulfuron **(11)** were poor (1–4%).

3.1.2 Determination Techniques

3.1.2.1 Liquid Chromatography Purified samples[40,52] were analyzed by HPLC with a Du Pont Zorbax® SIL column (25 cm × 4.6 mm) set at 35 °C and a photoconductivity detector. This detector is necessary in order to obtain adequate sensitivity and selectivity. A mercury lamp was used in the detector as it provided much greater sensitivity than a zinc lamp. Under these conditions, it was essential that the chromatographic system provided good temperature control of the column and reasonably pulse-free delivery of the mobile phase to minimize baseline fluctuations. Recoveries were measured on 16 spiked samples over a concentration range of 0.2–2.0 ppb for chlorsulfuron **(6)**, rimsulfuron **(12)** (see Table 3) and sulfumeturon-methyl. An average value of 80% was found with a standard deviation of ±16%. Coupled with extraction, cleanup, and isolation procedures, the method provided a means of determining sulfonylureas in soil and water at levels as low as 200 pg g^{-1} (0.2 ppb).

Powley and de-Bernard[43] report an analytical screening method for the determination of nine sulfonylurea herbicides in soil and water by LC with UV detection. The LOQs were 1 and 0.1 ppb in soil and water, respectively, for all herbicides. The samples were analyzed on a Zorbax® SB-Phenyl 4.6 mm × 250 mm column with gradient elution with acetonitrile, pH 2.7 phosphate buffer and pH 6.2 phosphate (1.5 mL min^{-1}) and UV detection at 245 mm. The soil and water recoveries are reported in Table 8.

Cinosulfuron **(7)**, thifensulfuron-methyl **(14)**, metsulfuron-methyl **(8)**, sulfumeturon-methyl and chlorsulfuron **(6)**[50] (see Table 3) were analyzed by HPLC using a 2-µm Microspher® C18 column (10 cm × 4.6 mm ID) operated at 30 °C with methanol–0.1% phosphoric acid at pH 3 (9 : 11) as the mobile phase, an injection volume

of 200 μL and UV detection at 226 nm. Linear calibration graphs were obtained for 5–250 $\mu g\,L^{-1}$. The recoveries of herbicides from freshly spiked soil samples and samples with aged residues at levels between 20 and 1000 $\mu g\,kg^{-1}$ were between 70–100% with RSD between 1–10% ($n = 4$). The detection limits in soils were ~5 $\mu g\,kg^{-1}$.

LC was performed[47] on a 5-μm waters symmetry C18 column (15 cm × 3.9 mm ID) with gradient elution (1 $mL\,min^{-1}$) with 20 mM phosphate buffer of pH 3.4 (solvent A) and acetonitrile (solvent B) from 30% B (held for 4 min) to 80% B over 25 min and detection at 220–230 nm. The primary wavelength for quantification was 225 nm. For some analyses, tribenuron-methyl **(15)** and thifensulfuron-methyl **(14)** were also determined at 262 nm. Recoveries were >85% except for tribenuron-methyl **(15)** (75%) and detection limits were <100 $ng\,L^{-1}$ for water samples.

Seven sulfonylurea herbicides,[49] thifensulfuron-methyl **(14)**, metsulfuron-methyl **(8)**, triasulfuron **(9)**, chlorsulfuron **(6)**, rimsulfuron **(12)**, bensulfuron-methyl **(13)** and tribenuron-methyl **(15)** (see Table 3) were analyzed by LC with UV detection and confirmatory analysis with an electrospray/mass detector. Volumes of 50 μL were applied onto a 5-μm C18 column (25 cm × 4.6 mm ID) with gradient elution (1 $mL\,min^{-1}$) with 3-mM acetic acid in acetonitrile or water (32–62% A in 40 min) and UV detection at 230 nm. Detection limits depended on the particular herbicides and were 0.6–2 $ng\,L^{-1}$ in drinking water (4-L sample), 2–9 $ng\,L^{-1}$ in groundwater (2-L sample) and 13–40 $ng\,L^{-1}$ in river water (0.2-L sample). The recoveries of 10–250 $ng\,L^{-1}$ compound from various water samples were >94%. Confirmatory analysis of the isolated material was performed by LC/MS using the same chromatographic column. The MS data were collected using a time-scheduled three-ion SIM (selected ion monitoring) program. Detection limits for herbicides by LC/MS were 0.5–3 ng.

3.1.2.2 Liquid Chromatography/Mass Spectrometry

Applications involving the determination of sulfonylurea herbicides have included thermospray LC/MS techniques, which have shown a lower LOQ in the range of 20 ppb. Continuous-flow fast atom bombardment (CFAB) LC/MS techniques using packed capillaries have also been used. MS/MS techniques provide additional structural information as well as higher specificity than single mass analyzers equipped with mild ionized ion sources. All these techniques are described below for several sulfonylurea herbicides.

Reiser et al.[53] proposed the application of microcolumn LC/CFAB/MS in environmental studies of sulfonylurea herbicides.

Shalaby et al.[41] introduced the use of thermospray LC/MS for residue analysis of sulfonylurea herbicides and their degradation products. Thermospray LC/MS has emerged as a versatile and selective technique that offers chromatographic separation, positive structural confirmation, quantification and sensitivity, which meet the criteria for multiresidue methods, especially for water-soluble and polar pesticides such as sulfonylureas. The method has been developed for two sulfonylurea herbicides (nicosulfuron **(11)** and rimsulfuron **(12)**) and a major metabolite of each, involves a simple extraction scheme and requires no specific sample cleanup prior to chromatographic analysis. The sample solutions were analyzed by HPLC on a Whatman Partisil C8 column (25 cm × 4.6 mm) with gradient elution (1 $mL\,min^{-1}$) with acetonitrile–0.1 M acetic acid followed by postcolumn addition of 0.5 M ammonium acetate buffer solution and thermospray ionization MS detection at m/z of 143–650. Recoveries for all compounds over four concentration levels are shown in Table 7. The average herbicide recovery was 88.3%, with an average standard deviation of 14.8% for the data population of 96 data points from 24 sample analysis. The LC/MS total ion chromatogram provides a typical profile of the soil studied and shows no interferences at the retention times for the four test compounds. The LC/MS ion chromatogram of a 0.02 ppm fortified soil, which is the lowest fortification level, showed good signal-to-noise ratio for the four test compounds at the method quantitation level.

Bossi et al.[42] report an LC/MS method with an electrospray ionization interface to analyze four sulfonylurea herbicides: chlorsulfuron, metsulfuron-methyl, thifensulfuron-methyl and tribenuron-methyl. MS analysis was accomplished by SIM of the deprotonated molecular ion in negative-ion mode. The four compounds were quantitated with the external standard technique based on the integrated abundance of the molecular ion $[M - H]^-$. Good reproducibility and high sensitivity (detection limits for the four compounds were between 0.002 and 0.005 $\mu g\,L^{-1}$) were achieved. MS/MS in selected reaction monitoring mode on a characteristic product ion (m/z 139 for chlorsulfuron **(6)**, metsulfuron-methyl **(8)**, and thifensulfuron-methyl **(14)**; m/z 153 for tribenuron-methyl **(15)**) was used as a confirmatory method. High sensitivity was also maintained with MS/MS, making it possible to identify sulfonylurea herbicides at very low concentrations.

Rodriguez and Orescan[44] analyzed 12 different compounds in water samples using electrospray LC/MS on a Zorbax® RX-C8 (5 μm) column (25 cm × 4.6 mm) fitted with a guard column (1.25 cm × 4.6 mm) of the same material with gradient elution from 20% (held for 10 min) to 36.8% of acetonitrile in 0.15% acetic acid during the following 21 min and then to 50% (held for 12 min) in

1 min and electrospray MS detection with SIM. The limit of determination was 0.1 ng mL^{-1} for all herbicides, and recoveries are reported in Table 9.

Determination of 18 acidic herbicides was studied with use of HPLC coupled via electrospray ionization with MS or MS/MS.[54] Analytes, chlorsulfuron **(6)**, metsulfuron-methyl **(8)**, thifensulfuron-methyl **(14)** and triasulfuron **(9)** were separated in a column (25 cm × 2 mm ID) of Hypersil® BDS C18 (5 μm). The gradient mobile phase (0.2 mL min^{-1}) contained 1 part acetic acid in 900 parts of methanol–H_2O (1 : 9 to 100 : 0 in 45 min). The electrospray voltage was 5 kV at a temperature of 250 °C and in both MS and MS/MS. SIM was from *m/z* 50 upwards. For the latter the collision gas was Ar at 1 mTorr and 10–30 eV. Detection limits using MS in the SIM mode were generally 0.4–0.5 μg L^{-1}, whereas detection limits were ten times higher using MS/MS detection.

Chlorsulfuron **(6)**, metsulfuron-methyl **(8)**, thifensulfuron-methyl **(14)** and triasulfuron **(9)**[46] were analyzed on a 5-μm ODS Hypersil® column (10 cm × 2.1 mm ID) with gradient elution (0.2 mL min^{-1}) with 10–80% formic acid (0.1%)/acetonitrile over 28 min and SIM/MS detection. Calibration was carried out at four concentrations over 15–170 μg mL^{-1}. The detection limit was <0.1 μg kg^{-1} and recoveries were 80–100%.

Li et al.[45] reported a determination using a triple quadrupole mass spectrometer operated in positive ion mode, via an ion spray under SIM conditions. The nebulization gas (60 psi or 413 700 Pa) was nitrogen and the curtain gas was (1.2 L min^{-1}) nitrogen. The collision gas, argon, was set at an approximate collision thickness of 250 × 10^{12} atoms cm^{-2}. Calibration graphs were linear for 0.05–10 ppb of each sulfonated urea. Suggested acceptance criteria for forensically valid data include a HPLC retention time reproducibility of ±2% and the selection of at least two and preferably three precursor product ions and an absolute abundance of ±20% for selected ions.

3.1.2.3 Capillary Electrophoresis Chlorsulfuron **(6)**, chlorimuron and metsulfuron[55] were analyzed using the capillary electrophoresis technique with an apparatus equipped with an untreated fused-silica capillary (50 cm effective length × 75 μm ID) operated at 25 kV and 35 °C. The electrolyte buffer was 30 mM sodium borate/80 mM SDS (sodium dodecyl sulfate) containing 14% aqueous methanol/20% aqueous isopropanol at pH 7 and detection was at 214 nm. The peak area was used for the quantitation of chlorsulfuron **(6)**, metsulfuron and chlorimuron. Calibration graphs were linear from 0.6–10 ppm of sulfonylurea herbicides with detection limits of 0.63 ppm for chlorimuron and 0.5 ppm for metsulfuron and chlorsulfuron **(6)**. Inter- and intraday RSDs ($n = 10$) were ≤4% and ≤2.4%, respectively. The mean overall recovery for the three herbicides was 95.4 ± 16.1%. For concentrations < 10 ppb the concentration was a limiting factor and HPLC was easier and more accurate than micellar electrokinetic capillary chromatography (MECC). Metabolites[56] of eight sulfonylurea herbicides (chlorsulfuron **(6)**, bensulfuron-methyl **(13)**, tribenuron, triasulfuron, ethametsulfuron, rimsulfuron, chlorimuron and metsulfuron methyl **(8)**) in aqueous solution were separated using the same apparatus. The only difference was the running buffer of 50 mM sodium borate/22 mM SDS/10% methanol at pH 8.

Capillary electrophoresis[48] was performed on a column (122 cm × 75 μm ID; effective length 100 cm) operated at 30 °C and 30 kV with a running buffer of 50 mM ammonium acetate of pH 4.75 in 12% acetonitrile and detection at 240 nm. LC was performed on a 5 μm Zorbax® RX-C8 column (15 cm × 2.7 mm ID) with gradient elution (0.25 mL min^{-1}) with acetonitrile/acetic acid and electrospray MS detection using a time-scheduled SIM (positive mode) of the M + H ions for each compound. The method was used to determine 12 sulfonylurea herbicides in water. Detection limits for LC/MS ranged from 0.01–0.12 ppb.

Bensulfuron-methyl **(13)**, sulfumeturon-methyl, nicosulfuron **(11)**, chlorimuron-ethyl, thifensulfuron-methyl **(14)**, metsulfuron and chlorsulfuron **(6)**[57] were separated, in the order cited, in a 57 cm × 75 μm ID capillary (effective length 50 cm) at 30 kV with (50 mM ammonium acetate buffer of pH 5.0)–acetonitrile (3 : 1) as running buffer and detection at 214 nm. On-column detection limits were 80–100 fM (injection volume 20 nL).

3.1.2.4 Gas Chromatography Thermally stable *N*,*N*′-dimethyl derivatives[58] for the GC analysis of chlorsulfuron **(6)** in Table 3 and metsulfuron-methyl **(8)** in Table 3, both model sulfonylurea herbicides, were produced by methylation of a 1 mL sample in ethyl acetate with 0.5 mL of diazomethane/ethyl acetate for 30 min. The solvent was evaporated under nitrogen and the residue was dissolved in 1 mL of toluene for GC analysis on a column (25 m × 0.2 mm ID) coated with HP-5 (0.33 μm) with temperature programming from 85 °C (held for 1 min) to 150 °C (held for 2 min) at 40 °C min^{-1}, then to 250 °C (held for 20 min) at 5 °C min^{-1} and ECD or nitrogen-phosphorus (N-P) detection. Peak identification was confirmed by GC/MS. The RSD were ≤3% and the calibration graphs were linear for 0.1–10 μg mL^{-1} **(6)** and **(8)** in Table 3. The detection limits were 50 and 100 pg for **(6)** and **(8)** in Table 3, respectively. Quantification limits were <0.1 μg L^{-1} for water and <1 μg kg^{-1} for soil. Recoveries in water were 94–120% and 84–114% for **(6)** and **(8)** in Table 3, respectively, with an RSD of 2–15%. The corresponding recoveries for soil were 59–104% and 65–121% (RSD 8–21%).

Crop determination has been reported only by Krynitsky and Swineford.[59] Grain samples were extracted with acetonitrile and partitioned with hexane. The combined acetonitrile layers were evaporated to dryness at 40 °C and the residue was dissolved in 0.05 M citric acid with sonicating. The resulting solution was cleaned up on an Isolute 5 CX cartridge. The sulfonylureas were eluted with 0.1 M ammonium acetate. The sample was collected and extracted with acetonitrile–CH_2Cl_2 (1 : 19, v/v). The organic extract was dried at 40 °C and dissolved in water. A solution was analyzed using a Model 270A-Ht instrument equipped with a fused-silica capillary (90 cm × 75 μm ID; 68 cm to detector) operated at 35 °C with an applied potential of 25 kV and UV detection. The running buffer comprised 50 mM SDS/25 mM NaH_2PO_4 adjusted to pH 6.15 with 25 mM Na_2HPO_4. The lower detection limit was ~0.02 ppm, except for rimsulfuron **(12)** and tribenuron-methyl **(15)** (0.035 ppm) (see Table 3). Recoveries were 72.9–118.5%.

3.1.2.5 Enzyme Immunoassay Kelley et al.[60] proposed a method for determination of chlorsulfuron **(6)** (see Table 3) in soil by enzyme immunoassay. They describe ELISA, a sensitive immunological technique that can monitor nanogram quantities of chlorsulfuron **(6)** in crude soil extracts. The ELISA technique is based on the ability of animals to produce highly specific antibodies to foreign materials. Antibody is collected from rabbit serum and becomes one reagent in a rapid solid-phase assay that is both specific and sensitive. The assay detects other sulfonylurea herbicides, which are chemically similar to chlorsulfuron **(6)**, but it fails to detect sulfonylurea with different chemical structures. The detection limit in soil was 0.4 ppb.

Other work helps to present a complete overview of all analytical methods for sulfonylurea herbicides utilized through the 1990s.[61–76]

ABBREVIATIONS AND ACRONYMS

ALS	Acetolactate Synthase
CFAB	Continuous-flow Fast Atom Bombardment
ECD	Electron Capture Detector
ELISA	Enzyme-linked Immunosorbent Assay

For pesticide residue determination, field sampling and analysis of agricultural soils and sediments requires the consideration of several seemingly interrelated factors. The mechanisms by which pesticides are adsorbed, absorbed, and desorbed from soils are not well understood for most families of chemicals or for most soils. In addition, soil properties are both spatially and temporally variable, so that the question of sampling methodology becomes important in order to insure that the samples taken are statistically representative of the larger population being examined. Thus, the investigator must weigh the attributes and limitations of each and then choose the best overall compromise among sample size and numbers, analyte specificity, and experimental designs. Following proper collection, the laboratory analyst must then choose among several options for selective extraction techniques for removal of the pesticide analytes of interest. For most applications, one of the following will be used: a classical approach employing a suitable solvent or cosolvent mixture in either a batch shake-out or Soxhlet extraction apparatus. Other more recently developed options include the use of extractant solvents or cosolvent mixtures held under elevated pressures and temperatures (pressurized fluid extraction (PFE)) or pure substances amended with cosolvent modifiers and held above their respective critical points (CPs) (supercritical fluid extraction (SFE)). Another option is the use of ultrasonic energy (sonication) to facilitate extraction. Each of these approaches relies upon an input of sufficient kinetic energy from an externally applied source to the sample slurried with extractant. As the binding energies responsible for the retention of pesticides on soil are overcome, sorbed solutes are released into the solution phase. Studies which address pesticide fate issues often also require determination of soil metabolite and degradate compounds along with the registered parent chemical. For many families of insecticides and herbicides, these same extraction protocols can be used to quantitatively remove the major daughter compounds from soils without requiring an additional extraction step.

1 INTRODUCTION

Soil is the basis of mankind's interactions with his environment because it is the interface between aquatic, atmospheric, and terrestrial ecosystems. Man's ability to manage soil for food and fiber production is a principal tool in combating global hunger and avoiding starvation. On many soils around the world food and fiber production is increased by the effective use of agricultural chemicals to combat a host of yield-reducing pests which attack or compete with crops and/or invade the soil volume. Beginning about 50 years ago,

numerous chemicals have been developed and marketed to farmers for the purpose of mitigating or eliminating pests, primarily insects, weeds, and fungi, which are responsible for reducing both the quality and quantity of harvested crops.

The use of pesticides to maximize crop production has grown steadily over four decades and the development and registration of new chemicals is continuing. In many areas of the world today it is common practice for producers to use combinations of chemicals on each field to control a variety of insects and weeds, either as a preplanting, at planting, or post-emergence application, all applied directly upon or into the soil. These farming operations, while producing a more abundant and higher quality food supply, also carry several unintended and potentially undesirable environmental consequences. For years many public and private institutions and agencies have sponsored research on the environmental fate and transport of the chemical legacy of pesticides used in agricultural production. As a result, it is now apparent that longterm use also yields several unintended outcomes. These include contamination of surface water (via runoff) and shallow groundwater (via soil profile leaching) resources in many areas, and diminished air quality wherever farming operations are conducted (via volatilization from plant and/or soil surfaces). Scientists studying soils have also suggested that the effects of longterm usage of pesticides may also include diminished soil fertility resulting from reduced or unintended shift in biodiversity within soil microorganism and macrofauna populations. Since pesticides are very often applied directly to soils it then becomes imperative to sample and analyze these materials when studying the environmental impacts of farming systems. If the goal is to quantify environmental water quality end-points, then some systematic soil sampling should be conducted parallel with the obligatory water sampling.

The purpose of any soil sample is to obtain information about a particular soil. The sample itself virtually is never the entire soil volume in which the investigator is interested. Therefore, this information from the sample is of interest only insofar as it provides information concerning the larger soil volume. For any soil sample, there are certain properties which describe it. In the broadest context, the purpose of sampling and analysis is to estimate these characteristics with an accuracy which will meet the data needs at the lowest cost. Sampling and analysis of agricultural soils following pesticide applications is a powerful tool through which to gain insight into the nature of the processes which result in both target pest control and potential environmental pollution. Soil sampling and analysis for pesticide content effectively supports many research goals including:

- Enhanced understanding of the cause-and-effect relationship between pesticide use for agricultural production at a given locale and observation of pesticide contamination of the surrounding environment.
- Enhanced understanding of the issues attendant to efficacy of the selected pesticide in controlling intended target pests and how soil properties and conditions might influence the response for a particular chemical.
- Delineation of the microbiological transformation processes which govern the environmental legacy in the soil for each pesticide.
- Support of transformation and transport studies in the field by delineation of soil residence time (half-life) for the parent chemical or family of chemicals within a soil series or combinations of materials.
- Experimental determination of soil affinity coefficients normalized for a soil series or to specific soil properties and useful to modellers as input parameters for model validation as well as pesticide transport simulations.
- Determination of specific potential for 'leaching to groundwater' by examination of the concentration gradient throughout the soil profile by analysis of small increments cut from continuous cores.
- Determination of surface loading from application in order to estimate losses to the atmosphere through volatilization from soil surfaces.
- Evaluation of agricultural soil as a test matrix for analytical chemistry applications; e.g. development of residue methods for new chemicals or for improvements of existing methods or for standardizing techniques against authentic reference materials.

2 THE OCCURRENCE OF PESTICIDE RESIDUES IN SOILS AND SEDIMENT

Soil is a complex living dynamic assemblage of organic and inorganic chemical components. The mineral matrix for most soils is a complex assembly of layered 2:1 phyllosilicate minerals bound together with interlayer metal bridges, most notably aluminum, iron, or manganese. Organic matter in soil is best viewed as a mixture of organic compounds which (a) vary in molecular weight from small monomeric electrolytes [such as the hexose monosaccharide glucose] to very large polysaccharadic electrolytes [such as plant starches or bacterial dextrans], (b) vary in stereochemistry and/or configuration, (c) vary widely in the functionality imposed upon both aliphatic and aromatic carbon skeletons, (d) vary greatly in their potential for electrostatic interactions,

and (e) lack the regularity of structure characteristic of many biopolymers, such as proteins, nucleic acids, and polysaccharides. Adsorption–desorption plays a paramount role in each physical process affecting the behavior of residues in soil. Pesticides are adsorbed by soil organic matter as well as by inorganic soil fractions, and the relationship between adsorption at both possible sites depends upon the specific properties of the soil (sorbent) and the pesticide (sorbate). Retention does not occur by a single mechanism, but rather is best described by a continuum of interactions. In general, binding energies for pesticide–soil associations fall within the 2–10 kcal mole range (van der Waals forces), much weaker than 50–100 kcal $mole^{-1}$ range for covalent bonds. This relatively weak interaction makes possible the extraction of residues by the techniques described herein.

As a class of commercially important synthetic chemicals, pesticides have come under scrutiny due to their wide-spread distribution throughout our terrestrial environment. Today more than 30 classes of chemicals with pesticidal properties are now widely acknowledged by most scientists and regulators, alike. Illustrating this diversity are the variety of chemicals registered for a broad spectrum of problems in weed, insect, and fungal control (Table 1). Nearly all of these chemicals represent post-World War II developments occurring in the last forty years.

Globally, the development of chemicals for control of weeds has proceeded much more rapidly than for other families of chemicals targeting insects, fungi, or other types of pests. In recent years, herbicides have accounted for approximately two-thirds of the global market for synthetic organic pesticides.

Table 1 Chemicals used for weed, insect, and fungus control

Herbicides	Insecticides	Fungicides
Arylanilines	Carbamates	Azoles
Benzoic acids	Organochlorines	Benzimidazoles
Bipyridyliums	OPs	Carboxamides
alpha-Chloroacetamides	Organotins	Dithiocarbamates
Cyclohexadione oximes	Oximino-carbamates	Morpholines
Dinitroanilines	Pyrethroids	OPs
Diphenyl ethers and esters		Phenylamides
Hydroxybenzonitriles		Strobilurine analogs
Imidazolinones		
OPs		
Phenoxyacetic acids		
SUs		
Thiocarbamates		
sym-Triazines		
unsym-triazinones		
Uracils		
Ureas		

SU, sulfonylurea; OP, organophosphate.

The nature of the association of a specific pesticide to a specific soil surface is largely governed by the interactions between functional groups. The major functional groups on inorganic surfaces which contribute to the adsorptive reactivity of pesticides are siloxane ditrigonal cavities contained in phyllosilicate clays and inorganic hydroxyl groups generally associated with metal (hydrous) oxides. Siloxane cavities are Lewis bases which create a net negative charge. Inorganic hydroxyl groups are the most abundant and reactive functional groups found on soil clays and are associated with the surfaces. Their specific reactivity varies depending upon both the number and type of coordination to metal ions. Soil organic matter includes polymeric organic materials, decomposing plant and animal residues, and soil microorganisms. A wide variety of functional groups are represented by the humic substances of soil. While the exact structure of humic substances remains elusive, most researchers agree that among its component chemical-types are large aromatic polymers composed of *N*-heterocycles, quinones, phenols, and benzoic acid derivatives. Recent studies employing infrared and magnetic resonance spectroscopic techniques have also identified carboxyl, carbonyl, phenylhydroxyl, amino, imidazole, sulfhydryl, and sulfonic acid functionality in soil humic materials. Soil humic materials also contain relatively high concentrations of stable free-radicals. The variety of functional groups identified in soil organic fractions along with the sterically and electrostatically controlled interactions between them results in a complex and continuous range of reactivities of soil organic matter toward pesticides. Thus, for any given pesticide, an increase in its polarity, number of functional groups, and ionic nature will all increase the number of potential adsorption mechanisms for that chemical. This is illustrated for the triazine herbicides, in which it has been postulated that van der Waals forces, charge transfer complexes, hydrophobic bonding, cation exchange, and cation bridging, all play a significant role in binding to soil.

3 FIELD SAMPLING, PREPARATION, AND PRESERVATION

Soil sampling is done in support of some types of field survey, which, in turn, are designed with a specific objective(s) in mind. There are five fundamental and interconnected essential steps to consider. First, an unambiguous objective for the sampling should be defined. A clear hypothesis needs to be developed from the question or issue to be researched. All ancillary

information deemed necessary for successful completion of the project should be assembled prior to the start of any experiments.

Second, a clear definition of what constitutes the variables characteristic of the population to be sampled across the field site. The selection of technique for determination is dictated by both the data requirements implied by the objective and the requisite minimal level of detection necessary for each analyte. As an example, for the location-in-space spatial aspect of soil sampling, is centimeter accuracy or minute of angle in latitude and longitude accuracy in the X and Y coordinate axes sufficient, and over what range or distance? For the chemical analysis aspect of soil sampling, what is the optimum sample size to be taken relevant to the minimum detection limit for the analytical method selected? Is a 50-g sample sufficient to achieve a chromatographic instrumental response distinguishable above background on an injection equivalent to 20 pg of pesticide analyte, or is a 2 kg sample required? Typically, in processing soil for pesticide residue determination, analysts have alternative means for adjusting instrumental responses for sample extracts which do not fall within the expected normal ranges. These include phase transfer, concentration, or dilution with solvent.

Third, the selection of an appropriate sampling plan designed in consultation with a skilled statistician is essential. Effective and thorough sampling regimes which indicate how many observations are necessary and at which points samples need to be taken can be categorized in two types. Classical, or design-based, sampling aims at estimating how much pesticide contamination is present. Alternatively, the geostatistical, or model-based, sampling aims to predict as accurately as possible where the contamination is present. In classical *systematic* sampling, sample units are selected at some equally spaced interval, resulting in a uniform distribution of observations over the entire population. Shortcomings to this approach lie in statistical probability in that not all locations within the population have an equal likelihood of being chosen for sampling. Another classical method, simple *random* sampling, allows for each location in the population to have an equal chance of being sampled.[1,2] Simple random sampling tends to undersample small, but potentially important, locations within the population.[3] In the combination of the two approaches, *random systematic* sampling, the locations within the population are arranged in some order, the first sample then randomly taken, and each subsequent sample then taken around that first sample using some fixed interval.[4] *Stratified random systematic* sampling allocates elements of the population into sub-populations based upon some chemical or physical property of the soil prior to sampling, then each stratum is randomly sampled.[5] Strata criteria might be based upon soil classification, slope of the terrain, or erosional class. This approach is considered to be the best option for geostatistical treatment of data because it avoids the possibility of bias resulting from periodicity in sampling locations.[6] Any test of the reliability of spatially distributed data requires assumptions regarding that distribution. Several researchers have criticized the use of classical statistics for treatment of spatially-distributed data, arguing that the conclusions are based upon assumptions not necessarily valid for spatially-dependent variables. The practice of using only a few sampling locations to characterize a spatially complex study area can be a major source error in spatial statistics. This issue is extensively discussed by Uehara et al.,[7] Lascano and Hatfield,[8] and Curran and Williamson.[9] Furthermore, many other sampling regimes exist.

Fourth, implementation of the survey with set procedures and protocols. All sample properties ancillary to the pesticide content and relevant to the objective must be sampled and determined as well and none should be omitted due to cost constraints. If necessary, fewer sampling sites is the best way to accommodate costs. The essential statistical support should be dictated by the sampling objective. Spatial uncertainty in the data is a consequence of taking an unnecessarily limited number of observations, and it can be avoided by taking more samples. Non-spatial uncertainty, such as that resulting from measurement error, can be reduced by repetition of the measurement or by increasing the accuracy of the measurement system. No two locations in any soil sampling regime are both temporally and spatially identical; therefore, a temporal variability experiment must be conducted in parallel time blocks in order for environmental data comparisons to be valid.

Fifth, performing an appropriate analysis(ses) with the given data. Visualization of pesticide residue data in three-dimensional formats is necessary to clearly observe the distribution of results. The extent of the distribution of pesticide concentrations is best presented in the context of soil volume data. In addition, linking the data to hydrologic models can provide insight into the mobility of pesticidal compounds through the soil volume.[10] A geostatistically based multidimensional visualization tool should be used to estimate and display the error or uncertainty associated with the spatial data. The use of the 'fill-in' tools, krieging or weighting, for estimating non-measured values by smoothing areas between sampled locations should be approached with caution, as they frequently can be taken to overrepresent the sampled information.

Depending upon the data requirements, a substantial saving of laboratory resources can be achieved through compositing of samples. A number of field samples are

thoroughly mixed to form a composite which is then subsampled for analysis. Composite sampling can be used in conjunction with stratification wherein each field unit is sampled and composited separately by stratum where it is known that the variabilities within the stratum are inconsequential. However, compositing of samples may result in a loss of spatial and temporal resolution of information.

Soil samples taken for pesticide analysis should be immediately placed in glass or Teflon® containers and sealed under screw-cap such that headspace is minimized. For pesticide determinations which commence with extraction, it is essential that samples be refrigerated as soon as possible, maintained under refrigeration until analysis, and analyzed as soon as possible. The most frequent changes in composition of soil samples during the time between collection and extraction are loss of volatile constituents, or biodegradation, oxidation or reduction of the specific pesticide residues of interest. Low temperatures reduce biodegradation and loss of volatile constituents, but freezing of water-containing samples can result in profound changes in the physical and/or chemical composition. Soil samples pulled from anaerobic zones must not be exposed to air. Typically, soil samples taken for pesticide extraction are not air-dried, nor are they ground to uniform particle size, nor are they screened or sieved, as is frequently done for determination of inorganic constituents, especially total elemental composition. Instead, a representative small portion of the thoroughly mixed bulk sample is taken for moisture determination and that value is then used to calculate a dry weight equivalent for the soil at its field moisture content. In the example, Equation (1) is used in the final calculation to compute analyte concentrations back to a dry-weight basis, and Equation (2) for calculating percent moisture in soil.

$$\text{Wt, dry} = \text{Wt, wet}\ \left(1 - \frac{\%\text{Moisture}}{100}\right) \qquad (1)$$

$$\%\text{Moisture} = 100\ \frac{\text{Wt, wet} - \text{Wt, dry}}{\text{Wt, Wet}} \qquad (2)$$

4 GENERAL CONSIDERATIONS FOR EXTRACTION

In order to extract a pesticide residue from a soil matrix and into an organic solvent phase, several interactions must be overcome and replaced with alternative interactions. The hydrogen bonding, van der Waals, and dipolar interactions between the pesticide molecule and its neighboring pesticide molecules and/or solvent molecules must be broken. The energy required to break these interactions generally increases with increasing polarity of the pesticide molecule. Once the pesticide is released from the matrix, it must be solubilized into the liquid solvent, which requires the breaking of interactions between solvent molecules. This can result from (a) weakening of the solvent–solvent molecule interactions so that they wet the soil surface sufficiently to disrupt the pesticide–soil interactions, or (b) weakening the solvent molecule network sufficiently to allow the pesticide to be accommodated into the solvent molecule environment. For polar solvents commonly used for extractions, the energy associated with this is larger than for less polar solvents, and can be estimated from surface tension and boiling point data alone.

Once solubilized into the solvent, the pesticide is enjoined into new interactions with solvent molecules as a stable solvent–molecule cage is formed. The stability of this interaction results in the release of binding energy, which is largest when the interaction of the pesticide and solvent is a more polar interaction. In order to achieve the maximum solubility in the shortest time, the energy barriers to solvation must be overcome. Increasing the temperature will result in increased rates for the interactions necessary for extraction to occur. Higher temperatures decrease hydrogen-bonding and dipolar interactions occurring on the relatively high energy surfaces of the soil. In addition, thermal energy reduces both surface tension and viscosity of the solvent, thereby enhancing diffusion. Heat will also disrupt stable lattice structures of the soil and impart a degree of kinetic energy to the pesticides. It will also decrease surface tension of the solvent and enhance diffusion. This results in a general decrease in solvent–solvent interactions, thereby accommodating pesticide molecules more easily into the solvent environment.

In analytical applications of soil extraction for pesticide residues, one important indicator characteristic for each chemical is its net molecular polarity. For most nonionic pesticides, polarity can be estimated from water solubility data. While pesticide association with soils material is mechanistically very complex, a useful rule-of-thumb for analysts choosing one among several extraction techniques is that water solubility and the soil-affinity coefficient usually enjoy an inverse relationship. The more strongly bound to soil are the pesticides, the more nonpolar and insoluble they appear to behave. Generally, more polar pesticides are best extracted from soil with more polar solvents or solvent mixtures. Table 2 presents water solubility range data for the most common families of herbicides, insecticides, and fungicides. Only the backbone structures which define the family are shown, as the specific substitution pattern for each chemical will also exert a great influence on extraction efficiency. Numerous resource materials are available which provide this type of information. The most widely used are the *Farm Chemicals Handbook*, updated annually and distributed by the Meister Publishing Co., Willoughby, Ohio; the

Herbicide Handbook, published by the Weed Science Society of America, and also distributed by Meister; the *Pesticide Properties Database*, compiled and distributed by USDA; and the *Pesticide Manual*, distributed by the British Crop Protection Council, Surrey, United Kingdom. For the nonionic pesticides, most have water solubility in the range of 5–500 ppm at 273–293 K. For ionic pesticides capable of forming stable cations or anions, or those which are formulated as salts, pH-dependent higher solubilities prevail.

Quantifying the efficiency of extraction for pesticide residues incurred in agricultural operations generally requires spike recovery studies. In the most widely practiced approach soils are amended with known concentrations of each target analyte, extracted, and the concentration in the recovered extract is determined by a suitable method, typically gas or liquid chromatography. Alternatively, radiometric analysis of soils amended with radioisotopically enriched congeners of the pesticide being studied is an often used technique in biodegradation studies. Percent recovery is computed as the measure of extraction efficiency. Underlying the validity of this approach is the assumption that the spiking procedure accurately and completely simulates the processes in the agricultural field by which pesticides, their degradates, and metabolites, become bound to soil. Native pesticide is probably retained by combinations of many binding mechanisms, some of which are not duplicated by most spiking techniques. The retention process, both adsorption and absorption is very complex, and may involve different mechanisms of association and all of the components of the soil: the organic and inorganic solid phases, the water phase, and the gaseous phase. For most pesticides, there is likely a continuum of mechanisms responsible for sorption onto soil. The spiking technique recommended here is less disruptive than most of the other recommended options because it does not involve elevated temperature, reduced pressure, mechanical agitation, or the use of organic solvents. For example, the use of large volumes of methanol may promote methanolysis reactions occurring either on the soil components or with the pesticide itself.

> ''Each sample used for recovery studies is spiked with a mixture containing each of the target analytes, by weighing 10.0 gm portions of a well-mixed 60-mesh dry-sieved soil into a 250-mL flat-bottom centrifuge bottle. An appropriate volume of spiking solution, 5–500 μL of acetonitrile solution prepared at a stock concentration of 100–200 mg L^{-1} for each target analyte is diluted with 25 mL of organic-free, distilled, and deionized water. The mixture is transferred quantitatively to the sample bottle. It is then stirred magnetically for several hours and evaporated to dryness (48 h) in an air stream, uncovered, in a fume hood. These air-dried samples are extracted directly without additional pre-treatment.''

5 THE FIVE MOST WIDELY USED TECHNIQUES

Classical methods for extraction of pesticides from soils and sediment materials generally involve the use of a solvent selected because of its optimum solubility with respect to the analytes(s) and its minimum solubility with respect to the sample matrix. In the simplest application, solvent is added to the soil sample while it is agitated to allow the analytes to dissolve into the surrounding liquid until all have been removed. This technique works well when the analyte(s) of interest are very soluble and the sample matrix is in a finely-divided and uniform physical state, or is very porous, thereby permitting closer association between solvent and solute molecules. When better contact between analyte and solvent is required, additional steps can be taken to insure maximum removal. The most popular of these for pesticide residue extractions are additional heating, additional pressure, and sonication, all of which require application of externally-applied forces to the soil–solvent mixture.

6 SOXHLET EXTRACTION AND SOLVENT-SHAKE EXTRACTION

6.1 Principle

Traditionally, solvent extraction has been the most widely used approach to removal of pesticides from soils. Techniques range from simple batch extractions using mechanical shakers to sophisticated devices which continuously recycle extracting solvent. By far the most widely used apparatus is the Soxhlet extractor (Figure 1). It was conceived and developed by German chemist Franz von Soxhlet (1848–1913) more than 100 years ago. In this device a soil sample is contained in a thimble of some porous fiber composition and positioned over a boiling solvent. More recently, glass extraction thimbles with fritted disk sealed in the base have become popular for soil–pesticide extractions. Any desired volatile solvent may be used, either water-miscible or water-immiscible. The solvent is heating to boiling, where it vaporizes. When it condenses, it drops onto the soil contained in the thimble, and extracts soluble compounds. When the liquid level fills the body of the extractor, the solvent containing the extracted pesticide is automatically siphoned back into the boiling solvent. After many cycles and many hours, the solvent is evaporated, leaving a residue for either further purification treatment or direct instrumental analysis. Over the years several modifications have been described, the best known being the Goldfisch technique. In this procedure, the

Figure 1 Soxhlet extractor. A, thimble; B, extractor body; C, solvent flask; D, condenser; E, siphon tube.

condensed solvent is allowed to drip into and through the sample thimble, immediately returning to the boiling solvent. It has no filling and siphoning action as in the original Soxhlet apparatus. Soxhlet extraction is simple, effective, and relatively inexpensive, other than the costs of solvent disposal. For many pesticides, it provides good analyte recovery. However, its traditional operation is slow and it requires large volumes of solvents. While extractions may last for 24 hours or more, they require very little user intervention once the process has begun. Small-volume Soxhlet systems are available, but the sample size often is dictated by the pesticide residue concentration, the minimum mass of analyte necessary for a representative sampling, and the chromatographic technique chosen for the determination. All of these often combine to require a larger soil sample size.

Through the years and through many improvements the original Soxhlet techniques remained time-consuming and prone to variability. By the mid-1970s a new accelerated solvent extraction (ASE) technique was described which reduced extraction time to as little as 30 min. Known as the Randall[11] modification, the sample thimble is totally immersed in the boiling solvent. The underlying principle is that the pesticide residue to be extracted is more soluble in hot solvent than in cold solvent at room temperature. This method has become the basis for many commercial automated solvent extraction systems derived from the original Soxhlet. Its limitations notwithstanding, Soxhlet remains the most exhaustive option available to the analyst.

6.2 Applications

Table 3 compares extraction efficiency, as determined by percent recovery, for a series of representative CHIs spiked onto clay samples for both conventional Soxhlet and automated Soxhlet techniques.[12] In every case, the Randall technique yields higher recoveries in a fraction of the time. While these data apply only to the nonpolar, very hydrophobic, low water-solubility insecticides, similar results are obtained with many classes of herbicides, including chlorophenoxy acids, triazines, chloroacetamides, and dinitroanilines. In recent years, automated extraction techniques have gained global acceptance as well as regulatory approval from the United States Environmental Protection Agency (USEPA). An exemplary USEPA approach can be found in the solid waste series, SW-846. Method 3541 describes the extraction of organic analytes, including many pesticides, from soil, sludge, and sediment by automated solvent extraction.[13] In addition to semivolatile organic compounds, which includes most pesticides, this method is applicable to polychlorinated biphenyls (PCBs) as well.

6.3 Advantages

Modern automated Soxhlet extraction offers several benefits over more traditional systems. The Randall boiling

Table 3 Comparison of extraction efficiency, as determined by percent recovery, for a series of representative chlorinated hydrocarbon insecticides (CHIs) spiked onto clay samples for both conventional Soxhlet and automated Soxhlet techniques[a]

Compound	Soxhlet[b]		Automated Soxhlet[c]	
	Mean recovery	RSD	Mean recovery	RSD
alpha-BHC	57.4	47.5	94.9	5.5
Hexachloro-benzene	55.4	24.5	81.7	7.1

DDT, 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane.

step accelerates the extraction three- to five-fold over conventional Soxhlet. Automated systems allow users to extract multiple samples simultaneously, thereby saving time and money. For many pesticides, especially hydrophobic nonpolar compounds, repeatability of recovery and efficiency are improved, often by more than 20%. Commercially available extractors use less solvent than conventional systems, require less fume hood space, and include built-in safety features with mechanisms designed to minimize unsafe operations.

The traditional Soxhlet procedure also offers several benefits for some users. It is often the method of choice for smaller laboratories due to its relatively modest capital investment. In addition, USEPA considers it to be the exhaustive extraction technique for removal of organic compounds from solid matrices, so that it has become the *de facto* benchmark for comparisons.[14]

Many of the newest generation of herbicides and insecticides are nonionic, very polar, and highly water soluble. Consequently their residues are easily removed from cultivated soils merely by contact with various aqueous solutions. Such is the case for the SU metsulfuron-methyl (CAS #74223-64-6), which is readily extracted from cultivated soils by frequent shaking of a slurry with a dilute solution of PBS, (phosphate buffered saline) solution for 30 minutes. Following centrifugation, the aqueous extract is acidified to pH = 3, and the metsulfuron extracted by SPE on polymeric-resin cartridges.[15] After elution with methylene chloride and solvent phase transfer, metsulfuron methyl is determined by high-performance liquid chromatography/tandem mass spectrometry (HPLC/MS/MS). Using this very simple and direct approach to extraction, a minimum quantitation limit of 200 parts-per-trillion is reported.

7 PRESSURIZED FLUID EXTRACTION

7.1 History

PFE is also known as pressurized solvent extraction (PSE), ASE, pressurized accelerated solvent extraction (PASE), and enhanced solvent extraction (ESE). In its rapid adoption of several new methods employing this approach, the USEPA recognizes PFE as its official name for this technique.

7.2 Principle

PFE[16] is carried out similarly to other techniques which utilize solvents well above their temperature and pressure at standard condition in that the solvent and the sample are placed in a closed container and heated. The heat is provided by an external oven and the solvent is pumped into and out of the extraction chamber. In this approach extractions are performed at temperatures of 373 to 453 K. In order to use common water-miscible organic solvents at these temperatures, pressures of 100 to 135 atmospheres are required to maintain the solvents in their liquid state. Under these conditions, analyte recoveries equivalent to those obtained from traditional Soxhlet extraction are achieved using much smaller solvent volumes for much shorter extraction times. Increasing temperature results in increased solubility, diffusion rate, and mass transfer, while viscosity and surface tension decrease. At elevated temperatures, the activation energy associated with desorption is more easily achieved and the kinetics of desorption and solubilization become more favorable.

The sample is enclosed in a high pressure stainless steel cylindrical cell. Following an initial heating period, it is allowed to interact statically with the pressurized solvent for a predetermined time, after which it is purged from the cell with nitrogen gas and collected in a vial. Since the extraction can be fully automated, samples can be run sequentially. Typical sample sizes for soils are in the 10–30 g range, and the total volume of solvent required for extraction and rinsing is in the 20–40 mL range. Extraction times for most pesticides are in the 20-minute range.

7.3 Applications

PFE is the most recently developed of the options analysts have for extracting pesticide residues from soils, with no published applications reports prior to 1995, and no commercial instruments available prior to 1996. Since then, however, a few applications have appeared in the research literature. Fisher et al.[17] used PFE to extract semivolatile organic priority pollutants from a red clay loam soil, both spiked in the laboratory as well as contaminated in the field. The analyte list includes two CHIs *p*,*p*′-DDT (CAS #50-29-3) and endrin (CAS #72-20-8). Spiking levels ranged from 400 to 20 000 ppb. At spike levels between 4000 and 20 000 ppb, recoveries approached 100%. At the 400-ppb level, recoveries were lower owing primarily to matrix interference. Conte et al.[18] report the extraction of diflufenican (CAS #83164-33-4), a pyrydylcarboxamide herbicide, from soil in 10 minutes using acetonitrile at 373 K at 30 atmospheres. Recoveries average 96% for soil spiked at 100–400 ppb. Four samples per hour are easily processed by this technique. While the high-performance liquid chromatography separation clearly shows coextracted material, presumably organic materials from the soil itself, none seemed to interfere with the retention time or shape of the herbicide peak. Pyle and Marcus[19] extracted seven CHIs from a standard reference material (SRM) marine sediment using (1 : 1) hexane–acetone at 373 K and 135 atmospheres in 20 minutes.

The insecticides included both *cis*-(CAS #5103-71-9) and *trans*-chlordane (CAS #5103-74-2), *trans*-nonachlor (CAS #3734-49-4), and the *p*,*p*′-isomers of 1,1-dichloro-2,2-bis(4-chlorophenyl)ethylene (DDE) (CAS #72-55-9), 1,1-dichloro-2,2-bis(4-chlorophenyl)ethane (DDD) (CAS #72-54-8), and DDT (CAS #50-29-3). Recoveries indicated that the combination of PFE together with quantitation by gas chromatography/tandem mass spectrometry (GC/MS/MS) is a complementary technique which is comparable to or better than existing techniques in terms of speed and sensitivity. In another report addressing chlordane extraction from soil, Brumley et al.[20] used (1 : 1) methylene chloride–acetone at both 373 K and 423 K for extraction completed in 20 minutes. Recoveries from soils spiked with between 2000 and 20 ppb ranged between 80 and 120% at 373 K.

PFE approaches have not been limited to insecticidal agents. The fungicide hexaconazole (CAS #79983-71-4) is effectively removed from weathered soils using acetone at 133 atmospheres and 373 K. Frost et al.[21] report that PFE furnished 'cleaner' extracts requiring no further pretreatment prior to chromatographic analysis than did either of two other high pressure systems. The nature of the hexaconazole–soil interaction is very important, although its ability to be recovered depends on extraction conditions and the efficiency of the system. Within the herbicide families of pesticides, triazines and chloroacetamides are two of the most widely used for weed control in corn and soybean. Gan et al.[22] have shown that PFE efficiently removes both atrazine (A) (CAS #1912-24-9) and alachlor (CAS #15972-60-8) from aged and freshly spiked soils. Following selection of a solvent system, a central composite statistical design was used to optimize extraction conditions by evaluating the effect of varying temperature, pressure, and static time on PFE efficiency. Temperature varied from 333 K to 413 K at 20 degree intervals, pressure from 33 to 166 atmospheres at 33 atmosphere intervals, and static time from 5 to 25 minutes at 5 minute intervals. A quadratic model was used to describe the interactions between each variable and the recovery. Following eight weeks of incubation the efficiency of PFE for both A and alachlor was consistently better than either Soxhlet or solvent extractions. As the herbicide on the soil ages, harsher conditions are needed to separate the residue from the matrix.

8 SUPERCRITICAL FLUID EXTRACTION

8.1 History

Experimental observations of a supercritical (SC) phase from which the property of CP for a pure substance was discovered date back to the early 1820s[23] when it was first observed that there is a critical temperature above which a pure substance can only exist as a fluid and not as either a liquid or gas. Appreciation of the solvating properties of pure substances above their CP date to 1879.[24] Early in the 1900s, it was observed that solubilities of nonvolatile organic compounds in carbon dioxide held under SC conditions were several orders of magnitude greater than that which could be explained from vapor pressure considerations alone.[25] Extraction with supercritical fluids (SFs) raised little interest during the first half of this century, and the interest shown focused on industrial process-based applications and not analytical chemistry. A new era for SFE was ushered in with a 1970 patent which described the decaffeination of green coffee beans by immersing the wetted beans in SC carbon dioxide.[26] Since 1980, there has been rapid development of applications of SFE within the food industry. At the same time applications in environmental analysis began to appear, although the initial reception by the analytical community was one of skepticism. Prior to mid-1989, fewer than 30 citations on analytical SFE could be found in *Chemical Abstracts*.[27] In the 1990s, the situation has reversed itself to such an extent that now more than 300 citations referencing SFE applications can be found in *Chemical Abstracts* for 1993 and 1994 alone.

8.2 Principle

In order to understand SFE it is helpful to review the properties of SFs. The physical state of a substance of fixed composition is described by a phase diagram, a pressure–temperature plot showing the relationship between the processes of sublimation, melting, and boiling. Shown in Figure 2 is the phase diagram for carbon dioxide. It defines the regions corresponding to the gaseous, liquid, and solid states. Points along the lines separating the phases define the equilibrium existing between the two phases. The vapor pressure of the substance begins at the triple point (TP) and ends at the CP. The critical region has its origin at the CP. Thus, an SF is any substance which is held above its critical temperature (T_C) and critical pressure (P_C). The critical temperature, therefore, is the highest temperature at which a gas can be converted into a liquid by increasing its pressure. Correspondingly, the critical pressure, therefore, is the highest pressure at which a liquid can be converted into a gas by increasing its temperature. At the CP, the densities of the two phases become identical. Thus, for pure substances held above their CP, there is only one phase and it expresses some of the physicochemical properties intermediate between those of a liquid and those of a gas. Viscosity is low and diffusivity is high, resulting in solvating power approaching polar liquids.

Figure 2 Phase diagram for carbon dioxide.

Using SFs for extraction of pesticides from soils offers several advantages. The solubilizing power, and thus the selectivity, can be adjusted in SFE by varying the density (changing temperature and pressure) of the SF. Often this results in cleaner extracts than liquid solvent extraction. This, in turn, reduces or eliminates the need for cleanup and facilitates quantitation by reducing analysis time while minimizing errors. By far, the most frequently used SF for pesticide extractions is carbon dioxide due to its relatively low T_C and P_C, low toxicity and reactivity, and availability in high purity at low cost. It has proven to be an excellent extractant for nonpolar pesticides, a reasonably good agent for moderately polar pesticides, and a poor extractant for polar pesticides. However, its effectiveness for the very polar analytes can be improved by the addition of polar organic solvents, known as cosolvents, as modifiers.

8.3 Applications

The use of SFE for extraction of many classes of pesticides from soils has received much attention in recent years. Most of this recent work has focused on current use insecticides and herbicides. Koinecke et al.[28] reported that the best efficiency for SFE of the insecticides fenpropimorph (CAS #67564-91-4), pirimicarb (CAS #23103-98-2), ethyl parathion (CAS #56-38-2), triallate (CAS #2303-17-5), and fenvalerate (CAS #51630-58-1) from soil was achieved using carbon dioxide with 5% methanol cosolvent at 330 K at 375 atmospheres pressure. Complete extraction of the insecticide chlorpyrifos (CAS #2921-88-2) and its major metabolite from soil using only subcritical water was reported by Jiminez–Carmona et al.[29]

Herbicides have also been a focus of SFE studies. Steinheimer et al.[30] removed triazine and chloroacetamide herbicides from two Iowa soils spiked at 100–2000 ppb range using cosolvent-modified carbon dioxide. A single extraction carried out at relatively high fluid density in both static and dynamic modes sufficed for all analytes. Principal component analysis was used to correlate the response of each analyte within a matrix of dependent variables influencing extraction efficiency. Polar pesticides, including the carboxylic acid herbicides, dicamba (CAS #1918-00-9) and (2,4-dichlorophenoxy)acetic acid (2,4-D) (CAS #94-7-7), are extracted from sand using in-situ derivatization under SFE conditions, followed by direct extraction of the derivatives. However, this technique is reported to be very sensitive to matrix effects.[31] Sand and a certified reference soil matrix were used to evaluate the extraction efficiency of carbon dioxide for 36 nitroaromatic compounds, 19 halogenated diphenyl ethers, and 19 insecticides.[32] SFE with methanol-modified CO_2 was compared with Soxhlet extraction for twelve pesticides, six CHIs and six OPs on four soil type materials: clay, sand, topsoil, and river sediment.[33] SFE was shown to have the best overall precision. The influence of both temperature and pressure on the extraction efficiencies of two *N*-phenylurea herbicides, diuron (CAS #330-54-1) and linuron (CAS #330-55-2), and a common metabolite from a sandy loam soil has been studied.[34]

SFE has been evaluated for extraction of SU herbicides from agricultural soils. Metsulfuron methyl (CAS #74233-64-6), sulfometuron methyl (CAS #74222-97-2), and nicosulfuron (CAS #111991-09-4) were studied on three Des Moines Lobe soils from the midwestern USA spiked at 400 and 4000 ppb. The extraction procedure was optimized for metsulfuron methyl with SF density, extraction time, and cosolvent addition, as the parameters studied.[35] Good recoveries (75–90%) for both metsulfuron methyl and sulfometuron methyl were obtained; however, only 1–4% of the added nicosulfuron was recovered. The authors concluded that SFE method optimization for specific compounds cannot always be extrapolated to similar compounds within the same pesticide family or to a different matrix, with respect to soil texture and composition, without additional method development and optimization.

The successes of SFs, amended or unamended, as extractants for trace organic analysis of soils and sediments has led some researchers to investigate the solvating power of liquids at elevated temperature and pressure, but well below their respective CPs.[36,37] Known as subcritical fluids, they have recently been applied to some pesticide applications. Crescenzi et al.[38] extracted eighteen herbicides from soil using 25 mL of subcritical water held at 363 K. The flow rate through the stainless steel cartridge containing 3 g of soil admixed with sand was increased from an initial 0.4 mL min^{-1} to 1.0 mL min^{-1}. The analytes consisted of both acidic

and nonacidic herbicides; the nonacidic chemicals largely from the *sym*-triazine and *N*-phenylurea families, and the acidic chemicals largely from the chlorophenoxy acid and benzoic acid families. Recoveries from both sand and silt loam soils spiked at 100 ppb ranged between 60 and 90%. This technique of subcritical water extraction is very similar to ASE with two distinct differences; first, pressures significantly above ambient are not required, and secondly, organic solvent use is either very small or not required at all. In an extraction method comparison with 12-h methanol Soxhlet versus a 2-h sonication in a methanol–water–acetic acid mixture, the subcritical water method yielded equal or greater recoveries than both other methods for both the acidic and the nonacidic herbicide analytes.

9 MICROWAVE ASSISTED EXTRACTION

9.1 History

In the 1980s, Ganzler et al.[39] conducted early experiments using household microwave ovens to aid in extraction conducted at atmospheric pressure. Since then, the process has been further investigated, refined, and patented. As a result, the technique has been successfully applied to extraction of organic compounds, priority pollutants, and volatile organics. That early development has resulted in specialized microwave instruments designed to provide temperature-controlled, closed-system operation.[40] These modern units permit heating of many samples simultaneously in closed, pressurized vessels which allow for heating of polar solvents to temperatures approximately 373 K above their standard conditions boiling points. Inertness of extraction vessel surfaces in contact with the sample is assured through the use of perfluoroalkoxy (PFA) liners.

9.2 Principle

The microwave portion of the electromagnetic spectrum is defined as energy of wavelength between 3 and 300 mm corresponding to a frequency range of 1–100 GHz. Microwave assisted extraction (MAE) is the process of using this energy to heat solid sample–solvent mixtures and results in the partitioning of the compounds of interest from the solid matrix into the solvent. Typically, extraction is done in a sealed vessel under temperature-controlled conditions. This results in extraction temperatures being raised above the atmospheric conditions boiling point for the solvent selected, thereby accelerating the extraction process. The closed-vessel microwave heating systems best suited for pesticide extraction from soil usually are outfitted with a turntable to rotate the sample within the cavity, thus insuring even distribution of thermal energy.

Microwave heating is significantly different from conductive heating methods. Conductive heating is sample independent. All samples placed inside a conduction heating oven will equilibrate to the preselected temperature, a process which can be quite slow. Microwave heating is much more solute-to-solvent ratio dependent. The rate of increase in the temperature depends on the microwave-absorbing characteristics of the sample. The cavity design provides the ability to heat several samples simultaneously and uniformly in a short time with the proper oven reflectile design.

9.3 Applications

MAE of CHIs has been described by Fish and Revesz.[41] Eleven compounds, including both cyclodiene derivatives and DDT-congeners, have been successfully recovered from certified reference soils spiked with each compound. A 1 : 1 acetone–hexane solvent mixture was used for extractions at selected temperatures between 363 K and 423 K with preset hold times of 15–20 minutes. Pressures ranged between 2.7 and 5.5 atmospheres. Results indicated that an extraction temperature of 293 K was the lowest at which recoveries were consistently at or above 95% for the reference soil spiked between 150 and 425 ppb for each CHI. Thermally labile CHIs, such as endrin and *p*,*p*′-DDT, showed no evidence of breakdown during the heating of the MAE process. Similarly, no loss of analyte could be attributed to the use of the PFA liners.

Successful application of MAE to pesticide removal in agricultural soils has not been limited to the hydrophobic and nonpolar end of the pesticide spectrum. A method for extraction of A together with several of its major soil metabolites has been reported by Steinheimer.[42] In this approach, A (CAS #1912-24-9), desethylatrazine (DEA) (CAS #6190-65-4), and desisopropylatrazine (DIA) (CAS #1007-28-9) are extracted simultaneously by subjecting a soil–aqueous phase mixture to rapid microwave heating, initially in water, and subsequently with dilute hydrochloric acid. The extracts are then recovered, combined, and taken to SPE (solid-phase extraction) clean-up and prepared for instrumental determination. Recoveries from two Iowa soils, a Des Moines Lobe glacial till and a Loess Hills silt, spiked at 100–10 000 ppb ranged from 60% for A to 80%–120% for both metabolites. MAE reduced extraction times from many hours to a very few minutes while conserving costly and disposal problematic organic solvents. In another study focusing on triazine herbicides, Molins et al.[43] report that MAE works very well for extraction of these residues from both freshly spiked soils as well as soils with spikes aged for up to 300 days. In general, the

freshly spiked soils yielded about 10% higher recovery than did the aged soils for DEA when using methylene chloride–methanol (90 : 10) as solvent, while A and DIA recoveries were nearly unchanged.

Among the most widely used newer classes of herbicides (post-1985 initial registration) used for both grass and broadleaf control in cash grain rowcrops are the imidazolinones and the SU compounds. Chemically, they are polar hydrophilic weak acids ($pK_a = 4$) with pH-dependent high water solubility. Extraction from soils by conventional methods is laborious and time-consuming. Stout et al.[44] report that imidazolinone herbicides are extracted from agricultural soil by MAE using 0.1 M NH_4 OAc in NH_4 OH as solvent at 398 K for 3 minutes. Average recoveries of 92% with a standard deviation of 13% are reported for soils spiked at the 1–50 ppb level. MAE together with solid-phase cartridge clean-up reduces the time required to prepare a set of twelve samples for instrumental determination to <10 minutes per sample. Better extractabilities are achieved both for surface spikes and for aged field-treated soils. Liquid chromatography/mass spectrometry (LC/MS) provides a 1 ppb limit of quantitation.

MAE is reported to be very effective in addressing the issue of 'bound pesticide residues' and their extractability. Nicollier and Donzel[45] have reported that MAE using 80% methanol in water at temperatures from 363 to 473 K effectively removed more of the ^{14}C residue, both parent and metabolites, than did cold extraction in both soils and biological tissue matrices. The addition of tetramethylammonium hydroxide (TMAH) drastically improved removal from biological samples, presumably as a result of hydrolytic breakdown of polymeric matrices or cleavage of pesticide adducts, releasing residue. Herbicides studied include dimethachlor (CAS #50563-36-5), metobromuron (CAS #3060-89-7), propiconazole (CAS #60207-90-1), cyprodinil (CAS #121552-61-2), and others.

10 EXTRACTION BY SONICATION

10.1 Principle

Principles underlying ultrasonic energy form the basis for the utility of sonication to enhance solvent extraction. Ultrasound is composed of sound waves transmitted at frequencies higher than those detected and discerned by the human ear. Ultrasonic energy generated by a piezoelectric transducer oscillating at a frequency of 20 000–40 000 Hz creates cavitation in liquids. Cavitation is the formation and collapse of countless tiny cavities or vacuum bubbles within a liquid. This energy causes alternating high- and low-pressure waves within the liquid as the waves alternately expand and compress the liquid. During expansion, tiny cavities grow at a microscopic level to a maximum critical diameter and then implode with release of the energy of the sonic wave. Localized vigorous agitation occurs at the soil surface during the contraction–implosion cycles, thus releasing sorbed pesticide from the surface and into the solvent.

Many parameters affect the strength of cavitation, including frequency and amplitude of the ultrasound, temperature, surface tension, vapor pressure, viscosity, and liquid density. Direct sonication uses a specially designed acoustic tool known as the horn or probe. The entire assembly, known as the sonotrode, is constructed of an inert material, such as a titanium alloy. The sonotrode is placed directly into a soil–solvent mixture. Horns and probes are available in different cross-sectional areas and lengths depending upon the solution volume to be processed and the desired intensity. Most of the energy associated with the sonotrode occurs at its tip, and the efficiency of energy transfer to this point is critical to the performance of the probe. The agitation also generates heat, and this heat can speed sonication extractions.

10.2 Applications

USEPA Method SW-846-3350 specifies sonication as one method for the extraction of nonvolatile and semivolatile organic compounds, including pesticides, from soils. The method is based on the expected concentration of organic compounds in the sample. A high-concentration method in which the concentrations of individual organic compounds are greater than 20 parts-per-million is simple, while the low-concentration method for components with concentrations less than 20 parts-per-million uses a larger sample size, and is more complicated. The sample (2 or 30 g, depending on the expected concentration) is mixed with anhydrous granular sodium sulfate to form a free-flowing powder that can be extracted three times or more using sonication. A solvent mixture of 1 : 1 acetone–methylene chloride is recommended for use with a specified horn-type sonotrode equipped with a titanium tip.[46] Sonication is a method of choice for extraction of polycyclic aromatic hydrocarbons (PAHs) and their hetero-atom analogs from sediments and soils but has enjoyed little adoption for pesticides. This is due to the greater popularity of alternatives, specifically, PFE and SFE, and ASE.

11 PESTICIDE BIOGEOCHEMISTRY IN SOIL: FORMATION AND EXTRACTION OF PESTICIDE-DERIVED COMPOUNDS

There are many different types of chemical reactions responsible for the conversion of pesticides to stable

daughter compounds in agricultural soils. Some are catalyzed primarily by consortia of indigenous microorganisms, including bacteria, fungi, and actinomycetes. Others are catalyzed by the surface functionality (such as dissociated silanols) found on clay mineral surfaces or the functionality of organic matter (such as carboxylic or phenolic acidity) present in the soil. In most cases, similar reactions occur for many members within a pesticide class. Within the CHI family of chemicals are both the DDT-congeners and the cyclodiene adducts. For the DDT-congeners, initial degradation in the soil proceeds through either of two breakdown pathways: hydrolytic dechlorination or reductive dechlorination. In the former, chlorine is replaced with hydroxyl, and in the latter, with hydrogen. The same type of pathway is observed for both DDD and DDE. In addition, DDT-congeners may undergo dehydrochlorination as well, as is observed in the conversion of DDT to DDE or methoxychlor (CAS #72-43-5) to methoxychlor olefin. For the cyclodiene adduct insecticides, those produced from Diels-Alder type cycloaddition of various olefins to hexachlorocyclopentadiene, initial soil breakdown usually proceeds through oxidation or dechlorination. In the case of aldrin (CAS #309-00-2) and isodrin (CAS #465-73-6), epoxidation occurs first, followed by dechlorination. In the case of dieldrin (CAS #60-57-1) and endrin (CAS #72-20-8), dechlorination occurs directly. A similar type scenario exists for the OP insecticides. All of the chemicals in this family of pesticides are derivatives of either ortho-phosphoric acid itself or one of its thiono- or thiolo-analogs. This circumstance is a consequence of the isoelectronic relationship between oxygen and sulfur, generally with either alkyl or aryl substitution. Initial degradation of OPs usually occurs via hydrolysis of one or more of these linkages giving rise to carbinol derivatives or their corresponding sulfur analogs. Thus, chlorpyrifos (CAS #2921-88-2) yields 3,5,6-trichloro-2-pyridinol as its major initial soil degradate, and parathion yields *p*-nitrophenol as its major initial soil degradate. Both carbamate herbicides and insecticides undergo hydrolysis in the soil, each yielding their corresponding carbinol or amine.

For the other major classes of herbicides, different types of breakdown reactions occur. *N*-phenylurea herbicides undergo hydrolysis to yield their corresponding aniline derivatives. In a report focused on fluometuron (CAS #2164-17-2), Mueller and Moorman[47] illustrate the degradation biochemistry and extraction protocol for this family. Degradation produces in sequence two *N*-demethyl derivatives in addition to the aniline derivative and all are efficiently extracted from soil by shaking with methanol for 30 minutes on a reciprocating shaker operating at 240 cycles per minute. Recoveries for a silt loam ranged between 30% and 90%, with the most polar metabolite, trifluoromethylaniline (CAS #87-12-7) yielding the poorest recovery. Rutherford[48] has extracted both parent and a soil metabolite of the benzamide herbicide isoxaben (CAS #82558-53-2) by refluxing a 50 g sample with 80 : 20 methanol–water for 1 hour. Clay loam and sandy loam soils spiked at 5–1000 ppb yielded recoveries between 70 and 95%. Both *unsym*- and *sym*-triazine herbicides undergo initial *N*-dealkylation reactions as well as hydrolytic dechlorination reactions. Chloroacetamide herbicides undergo both hydrolytic dechlorination to carbinol derivatives and hydrolysis to their corresponding anilino-derivatives. In addition, this family of herbicides undergoes conjugation reactions with soil components which lead to both sulfonic acid and oxanilic acid conjugates. SU and imidazolinone herbicides undergo hydrolysis reactions. For the SUs, cleavage of the sulfonated urea backbone produces aryl- or azaaryl-derivatives. Imidazolinones undergo a hydrolytic ring cleavage of the parent imidazolinone ring with the formation of carbamoyl carbamate derivatives.

Generally, and across most families of herbicides and insecticides, soil degradation initially produces daughter compounds which are smaller (lower in molecular weight), more asymmetric in structure, and more hydrophylic (owing to the incorporation of oxygen). As a consequence, they are efficiently extracted from soils by methods which can easily accommodate polar and water-miscible organic solvents. Depending upon the ionic nature of the degradates, dilute solutions of mineral acids or bases may enhance extraction efficiency by exploiting ion-exchange properties. Research papers specifically addressing extraction of soil metabolites and degradates mostly date from 1990 and include several of the techniques previously discussed. Exhaustive methods employed for extraction of CHIs from soils also remove structurally similar degradates with equal efficiency. Both DDE, the dehydrohalogenation degradate of DDT, and DDD, the dehydrochlorination degradate of DDT, are removed from soil along with DDT by any of the five highlighted approaches. Generally, if exhaustive extraction is the primary goal, without consideration of sample throughput, time, or solvent consumption and disposal, a variant of the Soxhlet technique remains the method of choice. Generally, for the OP insecticides, the same relationship prevails; techniques suitable for extraction of the parent pesticide also remove the initial soil metabolites and degradates with approximately the same efficiency. Thus, chlorpyrifos and 3,5,6-trichloro-2-pyridinol would be extracted simultaneously by any of the highlighted techniques.

For the major classes of herbicides, consideration of chemical properties of the target degradates makes the choice of extraction protocol somewhat more selective. In their report on SFE in which triazine herbicide

metabolites were extracted from two Iowa soils with methanol-modified CO_2, Steinheimer et al.[30] demonstrated that the process variables which exerted the greatest influence on the recoveries of the two A metabolites were carbon content of the soil and water content of the methanol cosolvent amendment. In the principal component analysis, these two parameters showed highest negative correlation with recovery for both DEA and, especially, DIA. Temperature, pressure, and both static and dynamic time intervals revealed lesser correlations with recovery. DIA recoveries from loam and silt loam soils averaged about 35%, while DEA recoveries from those soils averaged about 80%.

The application of subcritical water extraction to herbicide metabolites has recently been described by Di Corcia et al.[49] for the *sym*-triazine terbuthylazine (CAS #5915-41-3). This herbicide, which is not registered for agricultural use in the United States, is used as an alternative to A in Europe and elsewhere. Metabolites and degradates included all three desalkyl-metabolites: desethyl-, dest-butyl-, and desethyl,dest-butyl-. In addition, the corresponding hydroxyl derivatives of each of the derivatives were also included in the study of extraction responses. Both parent and daughter compounds are extracted together from 3 g of soil with phosphate-buffered water at 373 K. Extractant flow rate was increased from 0.3 mL min^{-1} initially to 1 mL min^{-1}. Analytes are trapped on a graphitized carbon black cartridge and recovered by elution. The subcritical water extraction was compared to two other methods proposed for the extraction of A and its degradation products from agricultural soils: 24-h Soxhlet extraction with methanol, and the room temperature mixed-mode extractant double extraction proposed by Lerch et al.[50] In comparison with the 24-h hot methanol extraction, the mixed-mode procedure gave the better recoveries, in spite of the fact that the soil was extracted only twice at room temperature. In contrast, the subcritical water procedure proved to be more effective in recovering the hydroxytriazine derivatives than was the mixed-mode protocol of Lerch et al.[50]

12 AUTHOR STATEMENT

With the exception of the Soxhlet approach all of these techniques have come into prominence only in the 1990s. Accordingly, many new applications are yet to be discovered and reported. As a consequence, the author views this discussion primarily as an educational tool and not as a reference work. He has, therefore, selected only citations which illustrate principles while providing well-documented examples referencing current literature at the time of publication. Accordingly, it is the author's wish that all readers will benefit from use not only of the references cited herein, but also of the references cited within those citations listed. Many of the listed references cite research reports in which the various extraction options have been evaluated comparatively against each other for a given extraction application. These are very helpful to the reader confronted with choosing one over the others.

12.1 Disclaimer

Mention of specific products, suppliers, or vendors is for identification purposes only and does not constitute an endorsement by the US Department of Agriculture to the exclusion of others.

ACKNOWLEDGMENTS

The author wishes to thank the following individuals for their support in providing resource materials for this article: Ms Shirley Anderson, Foss North America, Edin Prairie, MN; and Dr Greg LeBlanc, CEM Corporation, Matthews, NC. The author also extends his appreciation for their review comments to the following colleagues: Dr David Meek; Dr Thomas Moorman; Dr Richard Pfeiffer; and Mr Kenwood Scoggin.

Triazine herbicides and some of their transformation products (TPs) are included in both the European Communities and United States Environmental Protection Agency (USEPA) priority list of pesticides. Owing to their widespread use and toxicity profile this family of herbicides is one of the classes of chemical pollutants that are more intensively monitored by water authorities. Many analytical methods for their determination have been published. A critical overview of these methods is presented in this paper. Conventional extraction techniques are generally nonselective and can lead to analytical interferences caused by coextracted components present in the environmental matrices. Parameters affecting extraction and problems in isolating s*-triazines, from water, soil, urine and food are discussed. The solid phase is particularly attractive because it may be coupled on-line with chromatographic systems. Many extraction systems, in sorbent cartridge or disk format, have been developed in the last few years. Recently, interest has been growing in employing new highly selective materials such as molecularly imprinted polymers (MIPs) and immunosorbents to extract triazines from complex matrices. Strong cationic exchangers allow an effective clean-up and are useful to improve the sensitivity of a method. Solid-phase microextraction (SPME) is a new technique that can also be used for extracting analytes from water. This technique was successfully automated and coupled with liquid chromatography (LC). For solid matrices Soxhlet extraction is still widely used. Blending the sample in the presence of the solvent in high-speed homogenizer machines or in an ultrasonic bath ensures complete sample disruption and a better extraction of pesticides. Microwave-assisted solvent extraction, supercritical fluid extraction (SFE) and accelerated solvent extraction (ASE) are alternatives for conventional extraction procedures.*

Both, gas chromatography (GC) and LC were successfully coupled with sensitive and selective detectors, but because of the legal implications, the analytical methods need sufficient specificity for testifying contamination. It has been recommended that analytical results indicating the presence of relevant concentrations should be confirmed by mass spectrometric methods. The use of chromatography with mass spectrometric detector and the most common interfaces (thermospray (TSP), electrospray (ES) and atmospheric pressure chemical ionization (APCI)) are illustrated. Rapid screening based on immunoassay and biosensor technologies are described. Finally some examples of recent applications are summarized.

1 INTRODUCTION

The herbicidal activity of *s*-triazine was discovered in 1952 by a Geigy Co. research group in Bern (Switzerland).[1] The activity of this class of herbicides is based on the inhibition of the Hill reaction. The Hill reaction is one of a cascade of biochemical reactions which constitute the process of photosynthesis in chloroplasts. Some plants (corn) can degrade the Cl-triazine to an inactive compound by a reaction with a natural compound present in the plant (2,4-dihydroxy-7-methoxy-1,4-benzoxazine); some other plants (cotton) can store it in the lysigenous gland.[2] *s*-Triazines are predominantly applied in agriculture as selective pre- and post-emergence weed control of corn, wheat, barley, sorghum and sugar cane but are also widely used for nonagricultural uses (railways and roadside verges). The estimated worldwide annual consumption of atrazine[3] in 1980 amounted to 24×10^6 kg and the annual consumption of *s*-triazine herbicides[4] in USA (1992) exceeded 48×10^6 kg. Since it first entered the market in 1957, atrazine has been a very popular herbicide and in the last two decades has

Scheme 1 *s*-Triazine herbicide structures and degradation pathways.

become the most frequently detected pesticide in surface and groundwater.[5] Because of the occurrence in the environment Italy banned atrazine in 1990 and Germany followed in 1991. In the past few years common application rates for atrazine on crops have been 2–5 kg ha^{-1} of active ingredient, in 1992 maximum application rates were reduced to 0.25–0.6 kg ha^{-1}.[6] Since then, maximum label-recommended application rates have been reduced further.

Triazine herbicides are rather soluble and relatively stable in water: it has been estimated that between 0.3 and 1.9% of the applied amount of atrazine on farmland has found its way into stream water.[7] Their metabolites (Scheme 1) are frequently detected in groundwater. Differences in chemical structures are reflected in the physicochemical properties. *s*-Triazine characteristics are primarily determined by the substituent in position 2 (R_1 in Scheme 1). Their basicity increases in the order Cl < SCH_3 < OCH_3 (Table 1); pK_a ranges between 1.65 (simazine) and 4.46 (terbuton). The groups in positions 4 and 6 have smaller but pronounced effects on the basicity: the greater the number of alkyl groups, the more basic are the compounds.

Triazine herbicides and some of their TPs are included in both the European Communities and USEPA priority list of pesticides.[8] In the USA the new Food Quality

Protection Act took water into account to determine total human exposure to pesticides.[9] In order to evaluate the risk of cancer to general population by long-term exposure, in 1994 the USEPA placed the triazine herbicides into a ''special review''.[10]

Although in 1995 DuPont announced the voluntary phaseout of cyanazine (completed in 1999), a decline of the use of this family of herbicides is not predictable.

1.1 General Analytical Considerations

In Europe the maximum allowable concentration (MAC) of pesticides and ''related compounds'' in drinking water is set by the European Union Commission directive 80/778/ECC.[11,12] The directive states that environmental contaminants are not acceptable in water intended for human consumption and set MAC at $0.1\,\mu g\,L^{-1}$ per substance and at $0.5\,\mu g\,L^{-1}$ for the sum of compounds. In order to determine contaminants at the $0.1\,\mu g\,L^{-1}$ level analytical methods having a limit of detection of $0.02\,\mu g\,L^{-1}$ are needed.[8]

Trace analysis of polar compounds such as *s*-triazines in complex matrices poses serious problems:

1. When determining *s*-triazines and their TPs, poor recoveries from water by using either liquid–liquid extraction (LLE) or solid-phase extraction (SPE) with C18 bonded silica cartridges can be observed.[13–15]
2. Conventional extraction techniques are generally nonselective and can lead to analytical interferences caused by coextracted components present in the environmental matrices.
3. The analytical method needs sufficient specificity for testifying contamination. Because of the legal implications it has been recommended that analytical results indicating the presence of relevant concentrations be confirmed by mass spectrometric methods.[8]
4. A large-scale study will generate hundreds, if not thousands, of samples.

[a] M, transformation product (also referred to as metabolite); X, substituent (see Scheme 1).

ELISA, enzyme-linked immunosorbent assay; GC/MS, gas chromatography/mass spectrometry; PS-DVB, polystyrene-divinylbenzene; GC/NPD, gas chromatography/nitrogen–phosphorus detection; HFB, heptafluorobutyryl; ECD, electron capture detection; LC/UV, liquid chromatography/ultraviolet; FID, flame ionization detection; HRMS, high-resolution mass spectrometry; MAE, microwave-assisted extraction; GCB, graphitized carbon black; DAD, diode array detection; LC/MS, liquid chromatography/mass spectrometry; PID, photoionization detection; MS, mass spectrometry; SLM, supported liquid membrane.

Accurate analysis of all the samples would be prohibitive, so a low-cost, easily accomplished screening method should be used to select the sample for analysis with the confirmation method. This approach was tested in a large-scale study on herbicides water contamination and their metabolite transport in the ''Corn Belt''.[16] Due to their widespread use and toxicity profile this family of herbicides is one of the classes of chemical pollutants that are intensively monitored by water authorities. Many analytical methods for their determination have been published. An overview of these methods is presented in Table 2.

2 SAMPLE PREPARATION

2.1 Liquid Sample

2.1.1 Liquid–Liquid Extraction

Solvent extraction is usually carried out in a separation funnel, which is vigorously shaken to increase the contact area between the two liquids. The pH of the water sample is usually adjusted to 7 by adding phosphate buffer and, if necessary, H_2SO_4 or NaOH. The extraction efficiency is improved by adding salt (usually NaCl), which has the effect of weakening water–analyte interactions. In extracting *s*-triazines the preferred solvents are dichloromethane,[3,17] ethyl acetate[17] and a mixture of dichloromethane and ethyl acetate and ammonium formate.[18] After the extraction and phase separation, the organic phase is often dried with anhydrous Na_2SO_4. The volume of the extract is reduced using a Kuderna–Danish evaporator in a water bath at 65–70 °C. Often, solvent substitution is needed to make the final extract compatible with GC analysis.[19–24] The drawbacks of LLE are that it is labor-intensive, time-consuming and that it requires the use of relatively large volumes of pesticide-grade solvents, which are expensive, flammable and toxic. Even by using pesticide-grade solvents, concentration by a factor of 1000 or more can introduce analyte interferences by residual solvent impurities. Before use, NaCl and Na_2SO_4 should be heated at 400–500 °C for hours to eliminate potential interferences. Vigorous shaking of solvents and water, especially surface water, may create serious problems of emulsions because of the presence of natural or synthetic surfactants in the sample. Emulsions can be eliminated only by additional time-consuming operations. Finally, *s*-triazine herbicide TPs are less amenable than their parent compounds to extraction with organic solvents.

Large volumes of water are better handled by a continuous liquid–liquid extractor.[14] A drawback of this technique is that the extraction step takes several hours. Especially for more polar compounds – such as *s*-triazine metabolites – LLE is not the best choice.

2.1.2 Solid-phase Extraction

SPE is becoming the primary extraction technique for pesticides. Besides eliminating many problems associated with LLE, SPE is particularly attractive because it may be coupled on-line with chromatographic systems. Another feature of SPE is its adaptability to field extraction, by doing this organic pollutants can be isolated immediately from an aqueous matrix so that chemical and biological degradation can be avoided. Off-line SPE is commonly accomplished by forcing a water sample through the sorbent material in a small plastic cartridge by applying positive pressure or vacuum (Figure 1).

2.1.2.1 Nonspecific Sorbent In the last few years, filter disks consisting of C18 or polystyrene-divinylbenzene (PS-DVB) sorbents imbedded in an inert material have become commercially available for SPE. Advantages claimed for disk design over cartridge one are: shorter sample processing and decreased plugging by particulate matter due to the large cross-sectional area; reduced channeling effect; and a background cleaner from interferences (Figure 2). The latter advantage derives from the fact that, unlike SPE with cartridges, the extraction apparatus with disks can consist of glass.

The performances of these two types of materials on extracting *s*-triazine herbicides are compared by using gas chromatography/mass spectrometry (GC/MS) detection; this method allows a limit detection between 0.06 and 0.2 $\mu g\,L^{-1}$ in the full-scan mode.[25]

It has been shown that nonselective sorbents, as derivatized silica and apolar copolymers, allow determination of many pesticides at the 0.1 $\mu g\,L^{-1}$ level.[26–32] However, the main problem is the occurrence of many coextracted and coeluting interfering compounds. Determination of pesticides at nanogram

levels in surface water often requires an effective clean-up step. There is a trend to develop and apply more selective sorbents. A new sorbent material is graphitized carbon black (GCB). Due to the presence of chemical heterogeneities bearing a positive charge on its surface,[33] GCB can both be used as a reversed-phase sorbent and as an anion exchanger.[34] *N*-substituted *s*-triazines are adsorbed on the GCB surface by nonspecific interaction, but, by exploiting the GCB double nature, separation of triazines from coextracted acidic compounds (humic acids) can be easily performed. In this way extraction, preconcentration and clean-up can be performed with a single SPE cartridge.[14,35–37]

2.1.2.2 Immunosorbents Recently, interest has been growing in employing the highly selective analyte-antibody achieved by immunosorbents. In the immunosorbent, the antibody is immobilized onto a solid support and used as an affinity ligand to extract the target analytes and other compounds with similar structure from the aqueous sample. In this way, any component which is not recognized by the antibody is not retained, provided that there is no interaction with the solid support while the target analyte is bound to the antibody, leading to a high selectivity (Figure 3). Immunosorbent columns (with polyclonal and monoclonal antibodies) were used

to detect *s*-triazines in environmental water samples by liquid chromatography/ultraviolet (LC/UV) (diode array detection, DAD)[38,39] or liquid chromatography/mass spectrometry (LC/MS).[38,40–42] This technique allows high recovery (except for dealkylated triazines) of many *s*-triazines at levels of 0.01–0.2 μg L^{-1} (Table 3). Baker's yeast (*Saccaromyces cerevisae*) cells were immobilized on

silica gel for the selective preconcentration of *s*-triazines and their TPs.[39]

2.1.2.3 Molecularly Imprinted Polymers Production of antibodies is laborious, time-consuming and expensive. Selective polymeric material can be prepared by the synthesis of highly cross-linked polymers in the presence of a template or ''print'' molecule followed by removal of the template. The remaining polymer will contain binding sites, which are complementary to the template molecule. Single or multiple interactions can describe the linking of the analyte and/or template molecules to the monomers (Figure 4). The types of interaction can be hydrogen bonds, ion pairing, $\pi-\pi$ interaction or hydrophobic-effect-driven.[43] MIPs are chemically more stable than antibodies and can cope with higher temperature and a wide range of solvents and pH. Molecularly imprinted materials have been found to exert antibody-like affinities towards the target substances and can be used for selective extraction. Highly selective MIPs can be prepared to extract triazine from complex matrices.[44–49]

2.1.2.4 Supported Liquid Membrane This sample handling technique was developed by Audunsson in the mid-1980s.[50] It utilizes a porous polytetrafluoroethylene membrane, which is impregnated with organic solvent immiscible in water. The organic solvent forms a barrier between the sample and the aqueous acceptor, which the analytes have to pass to be extracted (Figure 5). The supported liquid membrane (SLM) technique can be described as a two-step LLE procedure in a flow system. It is typically applied to acidic or basic compounds, but recently also extraction of permanently charged components has been demonstrated.[51] A comparative study for the determination of methoxy *s*-triazines in

Figure 4 Schematic representation of the interaction of the analyte and synthesized polymer. The polymer contains several binding sites. The most favorable energetic interaction is shown at location A, where three binding sites result in the most specific interaction of the analyte with polymer. Two point interactions, which are energetically less favorable, are depicted at locations C and D, where the analyte is still allowed to rotate and, therefore, is less specific in its interaction with the polymer. Locations B and E show the least specific interaction possible and are, energetically, the least favorable.[43]

natural water by SPE and SLM has shown that a considerably cleaner extract can be obtained by the latter technique (Figure 6).[52] Various alkyl-*s*-triazines were enriched about 80 times from natural water.[53] However, the SLM procedure is slow and further improvements on this technique are necessary, especially the trapping of the analyte in the acceptor solution should be enhanced.[54]

2.1.2.5 Ion Exchanger Isolation of *s*-triazines, from water,[55] soil,[56] milk[57] and vegetable[55] extracts can be performed by using a strong cationic exchanger. Sorption of weak bases on a strong acid exchanger under strictly anhydrous conditions has been established to occur via

salt formation or hydrogen bonding.[58,59] This technique allows an effective clean-up and is useful to improve the sensitivity of a method.

2.1.3 Solid-phase Microextraction

SPME is a new technique used also for extracting analytes from water.[60] Figure 7 shows an SPME device. A 0.01–1 mm coated or uncoated fiber is immersed into a continuously stirred water sample. After equilibrium is reached (on average exposure times are 15–25 min), the fiber is introduced into the injection port of a gas chromatograph, where analytes are thermally desorbed and analyzed. Recently, SPME was successfully coupled with high-performance liquid chromatography (HPLC)[61,62] and automated systems have been developed coupling SPME with GC.[63] Parameters affecting SPME of triazine herbicides are salt effect, presence of humic acids, competition of major and minor components during the extraction process. In this experiment the polyacrylate phase was used and the sample was extracted over 30 min, followed by gas chromatography/nitrogen–phosphorus detection (GC/NPD) or GC/MS[64,65] (Figure 8a and b). Six *s*-triazine herbicides have been identified in groundwater well samples by an 8 μm polyacrylate fiber coating and GC/NPD.[62] The efficiency of this phase (85 μm) was also demonstrated by the time of extraction/desorption, pH and salt concentration study.[66] A multi-residue method for the simultaneous determination of 60 pesticides (atrazine, propazine and simazine included) was developed by using commercially available 100 μm polydimethylsiloxane fibers and GC/MS.[67]

2.1.4 On-line Solid-phase Extraction

In recent years, fully automated analysis of contaminants in water by on-line coupling of SPE to LC (Figure 9) or GC instrumentation has received increasing attention. Besides allowing rapid analysis, additional positive features of on-line SPE are that analyte loss due to evaporation does not occur and that the entire sample is introduced into the chromatographic instrument, instead of a fraction as with off-line procedures. In this way, the sampled volume can be reduced. In LC, when using a precolumn with a sorbent having a higher affinity for analytes than does the analytical column filling, broad peaks for the last eluted analytes

Figure 8 (a) Time dependence for the equilibration of the *s*-triazine herbicides between the aqueous and the polyacrylate phase. (b) Effect of desorption temperature.[66]

Figure 9 Set-up for the on-line trace enrichment of water samples where (-) represents load and (--) inject: (A, B) high pressure pumps; (C) extraction cartridge; (D) LC column; (E) detector; (F) recorder.

are obtained. In this case, backward elution of the analytes from the precolumn with the LC mobile phase can reduce peak broadening. SPE of *s*-triazine herbicides, using conventional reversed-phase materials (C18[68] or PS-DVB[69,70]), immunosorbent,[38] MIPs,[71] was successfully coupled with GC or HPLC with UV/DAD[40,41,68–70] and mass spectrometry (MS).[38]

2.2 Solid Sample

2.2.1 Soxhlet Extraction

Soxhlet extraction is still widely used, as it allows efficient isolation of pesticides from complex solid environmental samples. Adequate analyte recoveries depend on a suitable choice of the solvent. The extraction yields also strongly depend on the nature of the matrix. Weak basic triazine herbicides can be specifically adsorbed on soil and sediment particles, thus hindering efficient extraction of residues. To obtain an efficient extraction of organics from sediment and soil samples, the solvent should be able to penetrate into the pores of the matrix. Therefore, solvents having a relatively high surface tension should not be employed. Nonpolar solvents are often not suitable for extracting pesticides trapped in the core of soils and sediments, due to a poor wettability and limited miscibility with residual water present in the samples.[72–74] The wettability of a sample can be improved by just adding methanol and then the extracting solvent, for example ethyl acetate.[75] In a more recent study, methanol was used to extract a freeze-dried soil sample for 12 h.[76] The main drawbacks of this technique are the long time required by the extraction step and the large volume of solvent used. As an example, EPA method 3540 for extracting semivolatile organic priority pollutants, including some classes of pesticides, from soil or solid waste involves Soxhlet extraction with 300 mL of a solvent mixture for 16–24 h.[77]

2.2.2 Batch Extraction, Ultrasonic and Microwave-assisted Extraction

Blending the sample with a suitable solvent can be effective in many cases, blending the sample in the presence of the solvent in high-speed homogenizer machines or in an ultrasonic bath[78] ensures complete sample disruption and a better extraction of systemic pesticides.

Batch extraction of soil and corn samples with different mixtures of methanol, acetonitrile and acetone in a mechanical shaker for 90 min showed good recoveries.[79] Chloroform, dichloromethane, diethyl ether or methanol were used to extract terbutylazine and related TPs.[80]

Microwave-assisted extraction (MAE) is an alternative for the use of conventional extraction procedures. Water can be used to extract *s*-triazine herbicides and their TPs in a microwave oven while the sample is heated to 95–98 °C. This comparative study indicated that MAE with a mixture of dichloromethane–methanol (90 : 10, v/v) yields recoveries at least as good as those obtained by the conventional method. Moreover, the MAE procedure provides low solvent consumption in combination with a high sample throughput.[81]

2.2.3 Supercritical Fluid Extraction

SFE has been used in industry for many years, but only recently has it been employed in the analytical field for extracting a variety of pesticides from solid

Figure 10 Mixed-mode model for adsorption of hydroxyatrazine to soil. (Reproduced by permission from the American Chemical Society.)

matrices, such as soil, sediment, vegetables and animal tissues. SFE emerged as an analytical tool in the mid-1980s (Figure 10). Carbon dioxide modified with polar cosolvents, such as methanol or water, gives a high recovery of the polar analyte.[82] Chromatograms of SFE extracts reveal fewer coextractants than seen in conventional solvent extraction. Optimal conditions for extraction are dependent on both the analyte and the soil matrix. SFE has been applied for the analysis of atrazine and its dealkylated TPs.[83–87] SFE of *s*-triazines was also applied to freeze-dried water samples as pretreatment for GC/NPD analysis.[88]

2.2.4 Accelerated Solvent Extraction and Subcritical Water Extraction

ASE has been proposed as an alternative for Soxhlet procedures. With this technique, a solid sample is

Figure 11 Schematic representation of an SFE device.

Figure 12 Schematic representation of the laboratory-made subcritical water extraction device.

packed into an extraction cartridge and analytes are extracted from the matrix with conventional low-boiling solvents or solvent mixtures at elevated temperature (up to 200 °C) and pressure (up to 20 MPa) to maintain the solvent in the liquid state. ASE allows extraction within a short time and with a small amount of solvent. Water has been used at ambient temperature to extract sulfonylurea herbicides[89,90] and phenoxy acid herbicides[91] from soil. Very recently, Hawthorne et al.[92,93] showed the effectiveness of subcritical water in extracting chlorophenols, alkylbenzenes, polycyclic aromatic hydrocarbons and *n*-alkanes from a solid matrix. Class-selective extraction of these organics was achieved by adjusting the water temperature (50–300 °C). This finding was explained by the fact that the polarity of water decreases as the temperature is increased, thus making water more compatible with nonpolar organics for adsorption on soil particles or soil organic matter (Figure 11).[94] The hot-water extraction procedure can also be called accelerated water extraction. The extraction device used to extract terbutylazine and TPs from soil by using phosphate buffer (0.5 mol L^{-1}, pH 7.5) in subcritical water condition[95] is shown in Figure 12.

3 IDENTIFICATION AND QUANTITATION

The most frequently used chromatographic techniques for the analysis of the final extract are GC with

conventional and mass spectrometric detectors. Except for hydroxylated TPs, GC analysis of the *s*-triazine compounds can be performed without a derivatization step. In recent years, several multiresidue methods have been developed for identifying and measuring triazine herbicides by HPLC with UV or mass spectrometric detectors.

3.1 Gas Chromatography with Conventional Detector

Gas–liquid chromatography (GLC) on a packed column has been used extensively for the analysis of triazines with various detection methods such as flame ionization detection (FID),[96–98] electron capture detection (ECD),[75,79,99] photoionization detection (PID),[100] Hall electrolytic conductivity detection,[101] Coulson electrolytic conductivity detection[75,79] and thermoionic (or nitrogen–phosphorus) detection.[19,21,102,103]

Nitrogen–phosphorus detection (NPD) is particularly suitable for the determination of triazine herbicides (Figure 13), all of which contain five nitrogen atoms per molecule.The nitrogen–phosphorus detector is a modification of the conventional flame ionization detector in which alkali salt or alkaline-earth salt is placed in the flame (alkali flame ionization detector). This gave a response for N- and P-containing molecules comparable to that obtained with FID, but the response for other molecules was negligible. For a compound containing an N or P atom, the response may be 1000–10 000 times higher than that for the corresponding hydrocarbon. The NPD detector was also found to be about 10 times more sensitive for triazines than the electrolytic conductivity detector. To improve the sensitivity using other detectors many derivatization methods have been developed. Conversion of *s*-triazines into their heptafluorobutyryl (HFB) derivatives[104] improves the sensitivity 300-fold to several thousands fold with ECD and 5- to 10-fold with electrolytic conductivity detection in the halogen mode. Trimethylsilyl derivatives of hydroxy and amino derivatives, cyanuric acid, ammelide, ammeline and melamine were separated by GLC and detected by FID.[105] Although several USEPA methods still require the use of packed columns, GC with capillary columns, commonly referred to as high-resolution GC (HRGC) has become the standard for analyzing pesticide residues. Twenty-nine *s*-triazine herbicides and *N*-dealkylated TPs were separated on a high-resolution glass capillary coated with Carbowax 20M glass capillary column at 200 °C.[106] In a comparative evaluation with a capillary column the sensitivity was found to be five times higher than with a packed column.[107]

Figure 13 Analysis of triazine standards (1 ng each) by high-resolution gas chromatography (HRGC)/NPD: injection 250 °C, column, 30 m × 0.25 mm DB-1, 0.25 µm film; 70 °C, 0.5 min, 25 °C min^{-1} to 195 °C, hold 8 min; 10 °C min^{-1} to 200 °C: (A) prometone; (B) atratone; (C) propazine; (D) simetone; (E) atrazine; (F) prometryne; (G) simazine; (H) ametryne; (I) cyprazine; (J) simetryne; (K) cyanazine.[163]

3.2 Gas Chromatography/Mass Spectrometry

GC/MS is a well-established technique for the trace analysis of pesticides in environmental samples. This technique has benefited from the development of fused silica capillary columns, small relatively inexpensive mass spectrometers (quadrupoles) designed to be used as dedicated GC detectors, and sophisticated computer programs to perform computerized library searches.

Compounds eluted from the GC column enter the MS ion source where ionization of molecules occurs by impact with an electron beam. As a consequence, a series of ion fragments having characteristic mass-to-charge (m/z) ratios are formed. By scanning the MS over a defined m/z range, these ions are recorded by a photomultiplier or an electron multiplier and a resulting mass spectrum is obtained which displays m/z versus relative abundance. By summing the currents produced by each fragment ion and plotting vs time a total ion current (TIC) chromatogram is obtained (Figure 14). This chromatogram does not differ from those obtained with conventional chromatographic detectors. A much more sensitive method of quantitation of a target compound is that of plotting only one or few related ion masses from the TIC chromatogram. This method is called extracted ion chromatographic profiling (EICP). By EICP, accurate and sensitive analyte quantitation can be performed in the passage of a coeluted component, provided that two conditions are met. The first one is that the coextracted component does not produce the same selected ion. The second condition to be met is that the coeluted component does not affect the ionization process of the analyte. The maximum sensitivity with MS detection can be achieved by employing the selected ion monitoring (SIM) mode.

Figure 14 LC/ES/MS analysis of a spiked river water sample: (a) TIC chromatogram obtained by scanning the quadrupole filter from 40 to 220 m/z with 2-s scan time (sample spiked with 50 ng L^{-1} of *s*-triazine herbicides; (b) extracted ion chromatographic profiling (EICP) (same sample) of m/z 216 (molecular ion of atrazine); (c) selected ion monitoring (SIM) of two masses (m/z 174, 216) relative to the parent ion and the fragment ion from atrazine (sample spiked with 1 ng L^{-1}). The SIM and EICP traces are similar, but the ion signal of (c) was obtained by injecting 50-fold diluted sample.

Apparently, SIM looks like EICP. The former mode differs substantially from the latter one in that one m/z value is selected before the chromatographic run with SIM, the sensitivity of the analysis can be increased by a factor of 100 or more because the MS does not waste time to collect any other ion formed. Provided that the GC is able to separate all target components from each other and provides highly reproducible retention times, simultaneous SIM analysis for a number of analytes can be obtained by a time-scheduled program within a single chromatographic run, thus fully exploiting the potential of the MS detector. The weakness of the SIM operation mode by selection of one single ion for each analyte is that false positives can occur when analyzing pesticides in complex matrices. To avoid these false positives usually the molecular ion plus one or two characteristic fragment ions are selected for each analyte. In this way, quantitation can be performed by EICP of that ion which is not generated by the interfering compound. SIM by two or three ions can lower the sensitivity of the analysis to some extent, but greatly increases the accuracy. Analysis by time-scheduled SIM is the best compromise between sensitivity and specificity of the analysis. It is particularly useful when trace analysis of pesticides down to 100 ng L^{-1} in drinking water samples has to be performed for compliance with European standards. In this case it can be deduced that, considering that conventional GC injection devices permit introduction of 1 µL of a 500-µL final extract and that an easily interpretable background-subtracted spectrum with most MS detectors can be obtained by injecting 1–2 ng of an analyte, at least, the goal of obtaining highly diagnostic mass spectra cannot be reached by the full-scan acquisition mode. This situation however can be substantially improved by adopting large volume injector devices.

A complete study[108] on retention behavior and fragmentation under electron-impact and chemical ionization conditions shows that: (1) the differences in retention indices of the same triazines on a column with different polarity are proportional to pK_a values and to the dipole moments of these compounds; (2) under electron-impact conditions the stability of the compounds increases in the order chloro < methoxy < methylthio derivatives. Stable isotope dilution GC/MS was used for determination of low parts per billion concentrations of atrazine in water and soil.[109] An improved method (by high-resolution MS, HRMS) with lower detection limits allows the determination of triazine herbicides in parts per quadrillion range in groundwaters.[110]

3.3 Liquid Chromatography

Since several classes of pesticides cannot be analyzed by gas chromatographic techniques, official multi-residue methods based upon LLE/LC[20] or SPE/LC[111] with UV detection have been developed in recent years for a variety of pesticides including triazine herbicides and their metabolites in aqueous matrices. An additional feature of LC is that it can be easily coupled to both off- and on-line SPE. For analyzing *s*-triazines, the stationary phase is almost invariably silica chemically modified with reagents having an octadecyl alkyl chain. Commonly, this stationary phase is called simply C18. However, when analyzing basic pesticides, unreacted slightly acidic silanol

groups can play an important role in the fractionation process. The mobile phase is constituted by buffered water mixed with an organic solvent (usually methanol or acetonitrile). The triazine ring is a chromophore able to efficiently absorb radiations in the low UV region, that is, 210–240 nm. When operating in this region, the main drawback of the UV detector is that it can be classified as a quasi-universal detector. The main positive features of the UV detector are the high reproducibility and ruggedness, a broad linear dynamic range (10 000), a response virtually unaffected by the temperature and by composition of the mobile phase.

The most recent development in spectrophotometric detection has been the introduction of photodiode array detectors. Briefly, all the light from a deuterium lamp is passed through the sample cell onto the monochromator, which spreads out the beam into a spectrum. This falls across an array of 230–350 photodiodes mounted on a silicon chip (Figure 15). These can be read simultaneously by computer software to provide the full absorption spectrum from 200 to 700 nm every 0.1 s. In a simpler mode, the ratio of the absorption at two wavelengths can be used for analyte identification. This type of detector has a tenfold lower sensitivity in comparison to conventional UV detectors. Figure 16 shows a chromatogram obtained by analyzing 150 mL of a Seine River water sample by on-line SPE/LC/DAD. Apparently, peaks having retention times similar to those for simazine and atrazine were recorded. By comparing DAD/UV spectra, atrazine, but not simazine, was identified.

Figure 15 Schematic representation of photodiode array detector. (Reproduced by permission from Di Corcia.[162])

Using conventional DAD, the extremely wide range of pesticides can pose a difficult identification problem due to peak overlap. In addition, pesticides may coelute with other unknown sample constituents giving problems with quantitation. MCA, a technique that deconvolutes and quantifies known UV-absorbing substances in an unknown solution, can be used to examine the presence of a large number of pesticides from different classes in a single run.[70] With an on-line preconcentration of 200 mL of drinking water, detection limits ranged between

Figure 16 LC chromatogram and UV spectra obtained by analyzing a 150-mL sample from the Seine River. Comparison of standard spectra and unknown peak spectra for (a) simazine and (b) atrazine, where S refers to the standard and C to the peak of the unknown compound. (Reproduced by permission from Pichon and Hennion.[40])

10–50 ng L^{-1}. Because the UV spectra of *s*-triazine are not characteristic, DAD cannot always discriminate between triazines and matrix components. Selectivity problems in the LC analysis of *s*-triazines in real-life matrices can be resolved only by coupling LC to a mass spectrometer.

3.4 Liquid Chromatography/Mass Spectrometry

Nowadays LC/MS is applied in biomedical, pharmaceutical and environmental chemistry. For polar pesticides most of the technical problems of LC/MS have been solved and for many analytes the specificity and sensitivity with this technique are similar to GC/MS. Currently, the most popular LC/MS interfaces are TSP, particle beam, APCI and ES.

3.4.1 Thermospray

Besides separating solutes from the solvent mixture, the TSP interface is able to ionize compounds in solution at atmospheric pressure (Figure 17). Nonvolatile compounds can be ionized with TSP and detected with sensitivities comparable to GC/MS. Before entering the interface, the liquid flow from the LC column passes an electrically heated capillary with an internal diameter of 50–100 µm. Because of the partial evaporation in the capillary, a supersonic jet is formed that contains, in the presence of ionizing solvents, some charged droplets. Droplet charging occurs as a result of a statistical distribution of ions over the micrometer-size droplets.

Figure 17 Schematic representation of a TSP interface. V, voltage; HV, high voltage. (Reproduced by permission from Di Corcia.[162])

While passing the heated TSP source, the size of the droplets are more and more reduced, because of solvent evaporation. As a result, ions are expelled from the highly charged surface droplets, or ions are formed by gas-phase reactions. These ions enter the MS region through a skimmer. An electrode (the repeller), with a polarity equal to that of the ions of interest and set in front of the cone, forces ions into the MS system. Ion desorption from the surface droplet is achieved by the addition of a volatile buffer salt, typically ammonium acetate, added to the LC mobile phase. In most cases, ion evaporation shows $[M + H]^+$ ions for compounds with high proton affinity, such as *s*-triazine (Figure 18). Otherwise, $[M + NH_4]^+$

Figure 18 Mass spectra of (a) propazine and (b) terbutylazine. The top graphs represent TSP spectra, and the bottom graphs, particle beam EI spectra. (Reproduced by permission from Di Corcia.[162])

ions are formed. Owing to the soft ionization process, TSP spectra often do not display fragment ions. In some cases, fragmentation can be induced by using the discharge assisted TSP technique or by using higher repeller voltages. The device increases the kinetic energy of the ions; and the collision-induced decomposition (CID) process generates fragment ions. The specificity of methods involving TSP interface can be greatly enhanced by using tandem MS. TSP has been successfully employed in the analysis of *s*-triazines.[26,32,112,113]

3.4.2 Electrospray

The ES interface enables the LC/MS analysis of compounds with molecular weights up to 5 000 000 Da. Eluate of the LC column enters a chamber in which a high electrical field (3.5–4.0 kV) is imposed by a power supply. This electrical field causes an enrichment of positive electrolyte ions at the meniscus at the metal capillary tip. This net charge is pulled down field, expanding the meniscus into a cone (the so-called Taylor cone). If the electrical field is sufficiently high, the cone becomes unstable and filaments are formed from which positively charged droplets (positive ionization ES mode) detach and migrate towards the counter electrode. During migration, droplets shrink because of solvent evaporation caused by moderate heating and by a counterflowing gas (drying gas). It has been postulated that, when the surface concentration of the positive charges becomes sufficiently high, repulsion forces overcome cohesive forces and droplets explode generating daughter droplets (Figure 19). This process proceeds until the droplet radius reaches the Rayleigh limit. At this point, ion evaporation competes with further reduction of the droplet size. Any analyte capable of forming adducts with protons or other inorganic cations via ion-dipole forces can form ions in the gas phase in a variety of solvents. Moreover, the ionization process appears to be nearly 100% efficient, although not all of the ions formed are sampled. A cluster of ions with solvent molecules are sampled by a cone with a small orifice (100 μm) and pass into a first vacuum chamber (ca. 1 torr), called the dissolving chamber, where a supersonic expansion occurs. There, ions are declustered by collision with the residual molecules of drying gas. The core of the expansion is sampled by two skimmers, the second one set at about 20 V, and transported to the mass analyzer region (Figure 20).

Pneumatically assisted ES uses a nebulizer gas flowing coaxially with the liquid phase to create shrink droplets. With this device, the ES source can accept more than 1 mL min^{-1} of liquid phase (including water). Because the ES/MS arrangement is a concentration-sensitive

Figure 19 Schematic representation of the coulombian explosions of charged droplets in the ES source.

Figure 20 Schematic representation of the formation of fragment ions as a result of the collisions between $[M + H]^+$ ions and residual drying gas molecules.

detector,[114] diverting a fraction of the LC mobile phase to another detector does not affect the sensitivity. The problems arising from the presence of relatively high amounts of salts in the LC effluent have not yet been completely solved.

In the ES process, ionization is soft, leading to the formation of $[M + H]^+$ (positive ionization) or $[M - H]^-$ (negative ionization), even for most thermally labile and nonvolatile substances. Furthermore by increasing the electrical field in the dissolving chamber, the quasi-molecular ions can be accelerated so that multiple collisions with residual molecules from the drying gas occur generating characteristic fragment ions (Figure 21). The resulting CID spectra closely resemble those obtained by tandem MS system. In *s*-triazine LC/MS analysis addition of a low concentration (10^{-5} mol L^{-1}) of formic acid resulted in a 60% increase of ion signal.[115]

3.4.3 Atmospheric Pressure Chemical Ionization

Analyte ionization can also be induced by gas phase ion-molecule reactions under atmospheric pressure conditions. Reactant ion formation is achieved by the introduction of electrons from a corona discharge located in the chamber at atmospheric pressure. The discharge, occurring at the tip of a needle held at high voltage (4–6 kV), is routinely used in combination with both pneumatic and heated nebulization. This process allows formation of ions similar to those achieved with an ES source also for less polar components. Figure 22 shows an LC/APCI/MS chromatogram and spectra of a river water sample spiked with 1 μg L^{-1} of atrazine. A number of papers have been published on the determination of *s*-triazine using LC/APCI/MS.[24,116,117]

3.5 Immunochemical Assay

Immunoassays are detection methods based on a reaction between a target analyte and a specific antibody. Quantitation can be performed by monitoring a color change or by measuring radioactivity, fluorescence or other physicochemical properties. The recent rapid growth in immunochemical methods is attributed in part to the availability of polyclonal and monoclonal antibodies for a variety of components of environmental significance. Another driving force in the development of immunochemical methods is the need for rapid and simple tests that can be performed on-site without requiring sample transfer to an analytical laboratory. Many immunoassay-based field-portable methods enable rapid determination of target components by personnel without an analytical chemical training.

In a typical enzyme-linked immunosorbent assay (ELISA), a solid phase (beads or the wells of microtiter plates) is coated with a hapten–protein conjugate (Figure 23). A solution of a specific antibody that has been mixed with a calibration standard or sample is then added. During an incubation period, the analyte in solution and the hapten–protein conjugate immobilized on the solid phase compete for binding to the specific antibody. Washing with buffer removes excess antibody remaining in the solution and any antibody–analyte complex that has been formed. Then an enzyme-labeled secondary antibody is added, which will bind to the antibody captured on the solid phase. Alkaline phosphatase and horseradish peroxidase are commonly used as enzyme labels. An enzyme substrate is added, causing the development of a color. Absorbance or the rate of a color development can be measured with a spectrophotometer. Quantitation is based on competition for antibody-binding sites. In this assay format, color intensity is inversely related to the concentration of analyte in the sample. A single immunoassay takes 2–24 h and many samples can be processed in parallel. Also immunoassays can be easily automatized.[118] The disadvantage of this method is that the enzyme can be sensitive to matrix interferences. Control samples are necessary for quantitation of matrix effects and antibody cross-reactions.

Comparative studies can be carried out, using environmental samples, between immunochemical and conventional methods such as GC or GC/MS[16,118,119] or HPLC.[120] Time-resolved fluorescence immunoassay utilizes a fluorescent label and eliminates the need for an enzyme, thus making this method potentially less susceptible to matrix interferences.[121] A more rapid immunoassay[122] utilizes a specific antibody covalently coupled to a magnetic particle solid phase that has been shown to be more precise than methods using polystyrene-coated wells and tubes.[123] A screening test for determination of 0.15–4.00 ng L^{-1} of atrazine in drinking-, well- and surface water by magnetic particle immunoassay has been approved by the Association of Official Analytical Chemists.[124] A dipstick immunoassay format for atrazine[125] and terbutylazine[126] determination, based on the use of polystyrol strips as antibody coating support, can be very useful as a qualitative/semiquantitative "field test" for identifying "positive" samples.

3.6 Electrochemical Biosensor

A biosensor (or immunosensor) is a device that contains a biological component (e.g. enzymes, antibodies, or cell receptors) intimately connected to a transducer (e.g. electrochemical, optical, piezoelectric, or thermistor solid-state device). Whenever an interaction occurs between the target analyte and the biological component of the biosensor, some properties of the transducer

Figure 21 Background-subtracted CID spectra showing production of fragment ions from the $[M + H]^+$ ion for hydroxyatrazine by progressively increasing the electrical field in the desolvation chamber from (c) 20 V, to (b) 40 V, to (a) 50 V.

Figure 22 LC/APCI/MS spectrum and TIC chromatogram of 15 mL river water containing atrazine. Sample was preconcentrated with a short column system and acquired in full-scan mode. (Reproduced by permission from Springer-Verlag.)

Figure 23 ELISA format of a field-portable immunoassay. (a) Antibody is adsorbed onto a microtiter plate or test tube. (b) The sample and a known amount of enzyme-labeled analyte are added. (c) The analyte and the enzyme-labeled analyte compete for antibody-binding sites. (d) A chromogenic substrate is added for color production. (e) The color intensity, which is inversely related to the amount of analyte in the sample, can be estimated visually or measured with a spectrophotometer.

Figure 24 Schematic representation of an atrazine sensor.[128]

are altered and subsequently measured[127] (Figure 24). The substitution of membranes by MIPs of biological molecules in biosensors enables the development of a highly stable sensor that can be used in harsh environments.[128] Stable polymeric selective membranes have been used for conductometric[129] and fluorescence detection systems.[130]

4 RECENT APPLICATIONS

The occurrence of pesticides and other chemicals forced authorities to organize monitoring programs in order to evaluate risks from groundwater pollution. In these

programs *s*-triazines play a relevant role. In 1991, the US Geological Survey started the National Water Quality Assessment program (to be completed in 2002) to assess nationwide streams and groundwater quality in 20 of the USA major watersheds.[5] In this project (including analyses of 76 pesticides and 7 selected TPs) *s*-triazines were monitored by SPE followed by GC/MS determination. These data are the most extensive ever collected for such a wide range of pesticides and locations. A new computer tool ''Geographic Information System'' can easily map all these analytical data. Many other regional-scale monitoring programs were performed to assess the environmental water contamination by *s*-triazines. To curtail expenditure, analyses can be performed with low cost methods and confirmed by a mass spectrometric technique. This approach was used in a study on pesticides and TP transport. A rapid and inexpensive screening method such as ELISA was chosen because of its low cost per sample and GC/MS was used as the confirmatory technique.[16]

Occurrence and behavior of *s*-triazines in closed aquatic systems such as Swiss lake basins were thoroughly studied by SPE and GC/MS[131,132] or HPLC/UV[133] (DAD) analysis. The impact of *s*-triazine herbicides on open aquatic systems, such as estuaries, were performed by analyzing water and sediments in estuarine water of the Rivers Thames, Tamar and Mersey by SPE and HRGC with nitrogen-selective detection.[134] Another study was performed on River Ebro Delta water by LLE followed by GC/NPD and GC/MS as confirmatory technique.[135]

Groundwater can be contaminated by the leaching of pesticides. Many researchers studied the process that governs the accumulation and transport[136] or biodegradation[137,138] processes of *s*-triazines in soil.

Personnel that handle, mix or apply atrazine to corn and other crops face potential dermal and/or inhalation exposure. To estimate this potential exposure, excretion kinetics have to be known. Residues in urine of *s*-triazine and its dealkylated metabolites can be determined in urine at the parts per billion level by GC/MS.[139]

ABBREVIATIONS AND ACRONYMS

APCI	Atmospheric Pressure Chemical Ionization
ASE	Accelerated Solvent Extraction
CID	Collision-induced Decomposition
DAD	Diode Array Detection
ECD	Electron Capture Detection
EICP	Extracted Ion Chromatographic Profiling
ELISA	Enzyme-linked Immunosorbent Assay
ES	Electrospray
FID	Flame Ionization Detection
GC	Gas Chromatography
GCB	Graphitized Carbon Black
GC/MS	Gas Chromatography/Mass Spectrometry
GC/NPD	Gas Chromatography/ Nitrogen–Phosphorus Detection
GLC	Gas–Liquid Chromatography
HFB	Heptafluorobutyryl
HPLC	High-performance Liquid Chromatography
HRGC	High-resolution Gas Chromatography
HRMS	High-resolution Mass Spectrometry
LC	Liquid Chromatography
LC/MS	Liquid Chromatography/Mass Spectrometry
LC/UV	Liquid Chromatography/Ultraviolet
LLE	Liquid–Liquid Extraction
MAC	Maximum Allowable Concentration
MAE	Microwave-assisted Extraction
MIP	Molecularly Imprinted Polymer
MS	Mass Spectrometry
NPD	Nitrogen–Phosphorus Detection
PID	Photoionization Detection
PS-DVB	Polystyrene-divinylbenzene
SFE	Supercritical Fluid Extraction
SIM	Selected Ion Monitoring
SLM	Supported Liquid Membrane
SPE	Solid-phase Extraction
SPME	Solid-phase Microextraction
TIC	Total Ion Current
TPs	Transformation Products
TSP	Thermospray
USEPA	United States Environmental Protection Agency

Hydrocarbons Analysis: Introduction

Peter A. Nick
Process Systems Engineering, Yorba Linda, USA

The progress of inorganic chemical analysis technology has historically been dependent upon profit motives. Medieval alchemy was driven by the need to turn base materials into treasure. During the Enlightenment, scientific chemistry work was somewhat less commercial but still typically funded by a patron intent on deriving some specific benefit. Often the true benefit(s) discovered was not what was originally intended or expected. This is a normal occurrence in science and is what keeps most of us motivated to continue to work and study in this field. Still, economic justifications are the historic motivators for most practical advances. The Industrial Age, for example, demanded the implementation of efficient ore discovery, analysis, and conversion to metal for construction and fabrication purposes. Many of the basic quantitative wet chemistry methods owe their genesis to the late 19th century when large-scale mineral mining efforts became a matter of routine and chemical analysis of the ore a part of the process.

Another significant area of fundamental chemistry also has its root in commercial opportunism. Read any organic chemistry text and one finds that the first half of the book will discuss the wide and varied chemistry of the hydrocarbon – particularly those of petroleum-derived origin.

Although originally thought of as a medicinal base, wick-lamp fuel, or coating material, crude oil and its derivatives were completely unappreciated until two somewhat independent events occurred. First, a vast array of crude oil and gas hydrocarbon reservoirs were found in the time period of the mid-1800s (Pennsylvania) through the first decade of the 20th century (east Texas and other locations). The main products distilled from this oil were fairly low-volume and low-profit retail products for consumer consumption, of the types noted above. The gas associated with the oil was sometimes burned in municipal lighting facilities but only if it did not have to be piped very far from the source. As a result, it was often flared and burned for disposal. The big nuisance product of early petroleum processing consisted of a lighter-than-water, clear liquid phase, called petroleum naphtha or ''white oil'', which had a disturbing tendency to catch fire too easily and even explode violently under certain conditions. It made a wonderful solvent but was far too dangerous to be used in any significant amount by consumers and manufacturers. It usually was burned, like the gas, for disposal and was worth next to nothing, its supply far outweighing demand.

The second key development involved a technology which when commercialized would revolutionize the world and provide one of the biggest economic development engines in the history of mankind. The combustion engine, in its varied forms, was this invention, specifically the higher pressure petroleum naphtha injection-fueled version we know today. Initial engine schemes for mechanical land transport developed independently of the oil product gluts. They would utilize any type of fuel such as wood, bagasse, coal, or nearly anything else that could burn. Later versions used the heavier kerosene and gas oil streams from crude oil refining as these were reasonably abundant and relatively safe to handle. For several years overall demand for these first ''mechanical horses'' was limited and competition among engine types flourished.

It was when automobile makers discovered that high-compression ignition engines optimally combusted this cheap abundant material that events moved rapidly. With a growing worldwide consumer class wanting the freedom of personal transportation and two world wars demonstrating the military value of this engine technology, crude oil was soon being produced solely for its naphtha value, with the more traditional products being relegated to side-stream status. More and more research effort was put into understanding the chemistry of fuel hydrocarbons and finding ways of increasing this naphtha material production. For geographical areas deficient in petroleum, Europe and Germany in particular, derivation of naphtha-like material from much more abundant coal resources proceeded on a priority basis. The wartime fuel production efforts, especially the work to discover a means to synthesize rubber from oil, catalyzed the analysis work in all areas of hydrocarbon processing. The global economic booms in the latter half of the 20th century provided even more extreme incentives for the petroleum refining market to grow. Refinery process needs for base fuel production and requirements for increasingly stringent fuel performance specifications made analysis of these pure hydrocarbon systems a priority industrial activity. A host of derivative petrochemical and oxygenated organic chemical industries sprang up, in turn, from the roots of petroleum refining. Analytical procedures for each industry started from those used in the laboratories of the refining plants that fed them and were quickly extended into their own specific domains of need. Many of the newest analytical techniques still rely on this legacy of data to extend and validate the measurement results they produce today.

The vast portion of this technology growth occurred in the 30 years after the Second World War. During this

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

''golden age'' of refining, a massive knowledge bank of hydrocarbon chemistry information and analytical techniques was formed, much of which has been reported in the public domain. The detail with which we know pure hydrocarbon organic chemistry is due largely to the incentives generated by this unique set of historical and economic conditions. Today, this boom-time research and development activity appears to be at work in the biopharmaceutical industries.

The industrial hydrocarbon production and processing sector is now considered a mature entity. It is in commodity-production mode with low relative margins but its products are still demanded in huge quantities. Like all such low-profit (taxes are the biggest pump cost, not refinery margin, for those readers who dispute this contention), high-volume industries, cost reduction becomes a major business strategy and innovation takes a back seat to the needs of meeting revenue-production quotas. Downsizing and mergers of key industrial participants have greatly reduced the number and funding of scientists engaged with primary research into hydrocarbon systems. This malaise has affected both the industrial and academic sectors. Oil is no longer ''sexy'', as it were.

A new concern – and cost generator – is that of environmental remediation. Once the public domain was thought of as a free sink in which to put wastes. As a society, we have made waste minimization and elimination just another cost of doing business – with public health issues and the attendant costs of such rightly being of considerable concern in the value-accounting process. The analytical needs of this ''green'' technology protocol are being driven by cost factors once again, although the current incentives are essentially negative ones (do it or else get fined!).

At the same time, analytical reporting accuracy needs went from parts per million levels at the extremes of analysis to our current parts per billion and trillion exposure levels. Many of the initial techniques regulators and industry used for environmental analytical work were developed by refiners during the ''golden years'' alluded to above. Improvements to these methods, particularly for wet chemistry and heavy hydrocarbon analysis, were inevitable and today a whole new discipline of environmental analytical chemistry has evolved. This encyclopedia has a major subsection devoted to the discussion of environmental and regulatory analyses of industrial wastes and the processes that produce them. Examination of these volumes by readers would provide an excellent auxiliary source of analytical techniques to complement what is presented herein. In fact, once you have absorbed what is presented in this volume, examine the remainder of the encyclopedia. Many of those techniques can be and have been successfully used in laboratory work dealing with any organic material.

While mature, the hydrocarbon production and refining sector, particularly the fuels sector, is hardly dead, despite press reports to the contrary. The unique chemical paradigm of crude oil and traditional products, i.e. hundreds of different species distributed in a wide range of molecular size, has long been a constraining factor on the type and complexity of petroleum and petroleum product analyses. Traditional analyses usually measure quantities specified in terms of some easily defined inspection parameters, boiling point and gravity being the most common.

Most newer methods of analysis that can define chemical species concentrations of the order of parts per trillion must take advantage of higher resolution analytical instruments that the computer and embedded control chip revolution has spawned. The coupling of the primary measurement hardware with powerful data and calculation servers provides a wealth of information about any material quickly. This new technology has allowed commercial hydrocarbon stocks now to be speciated and type-categorized down to the heaviest reaches of the molecular weight distribution curve. This, in turn, has opened up new vistas for the production facilities to monitor and control the processing of many potentially hazardous compounds, either to limit their production or to replace them in the process altogether. In a turn of poetic justice, high-performance liquid chromatography (HPLC) techniques originally developed for regulatory analysis of aromatics in wastewater are now used to quantify the same species in refinery conversion units such as catalytic cracking and naphtha reforming.

This symbiotic approach across industrial areas is a recurring theme in all sectors of the chemical process industries, not just the hydrocarbon sector. Knowledge begets knowledge, as one saying goes; thus we owe a debt of gratitude to those who expanded this once nascent field of knowledge into the vast array of analysis techniques available to chemists today. Just read the contents of this encyclopedia to see how much progress has been made. One cannot hope to cover the wide array of methods and techniques in use or in research today. We have tried to retain a representative sample in this volume of what currently seems to be valuable to the hydrocarbon production and refined product industry. If there is a bias towards fuel production, it is because this is still a huge economic factor in our world and will continue to be so long after the pages of the volume you read here have disintegrated into pieces. Economics still drives the development of analytical chemistry technology. Thus the reader will find the present emphasis on petroleum-based analytical environments. Refiners still pay most of the bills!

By way of categorizing the contents of this section, we include five articles on specific methodologies as applied more to product analyses of various hydrocarbon intermediate or product cuts in general.

Dr Klawun's **Hydrocarbons: Gas Chromatography Procedures for On-line and Off-line Analysis** extends the discussion of gas chromatography (GC) methodology to the analysis of hydrocarbon mixtures originating from mineral oil sources as well as providing an overview of GC and detectors, including hybrid instrumentation.

The article **Mass Spectrometry, Low-resolution Electron Impact, for the Rapid Analysis of Petroleum Matrices**, by Drs Nero and Drinkwater, focuses on some currently nonstandard methods which can be used to determine the composition of individual components or classes of components within various petroleum matrices. GC coupled with low-resolution mass spectrometry – gas chromatography/mass spectrometry (GC/MS) – is the most useful method for *quickly* identifying and precisely measuring specific components or classes of components in a petroleum matrix. Direct insertion probe tandem mass spectrometry (DIP/MS/MS), used for less volatile and thermally labile petroleum components, is covered is some detail.

A ''one-stop'' laboratory methodology is presented by Dr S.E. Scheppele using similar but more sophisticated and ''intelligent'' technology. His article entitled **Mass Spectrometry, High-resolution, (Homolog)-type Analysis of Petroleum and Synfuel Distillates and Refinery Streams** describes what may well be the preferred methodology of the future. Several practitioners of this type of analytical system currently exist. Most are developing their homolog databanks in confidentiality. Dr Scheppele is to be commended for his willingness to discuss the University of Illinois efforts here in our compendium.

Dr Mizaikoff's contribution on **Fuel Performance Specifications, Mid-infrared Analysis of** covers an old technology with a fairly new spectrophotometic frequency range – at least as applied to fuels analysis. Most spectrophotometric work with hydrocarbons today covers the near-infrared frequency range. It is often adequate for quick or even ''on-line'' results but usually not too accurate unless repeatedly recalibrated or used in conjunction with one or more alternative analyses such as GC or nuclear magnetic resonance (NMR) spectroscopy. The authors here present a case otherwise – at least for the mid-infrared spectrum methods.

A current ''hot topic'' for refinery process control is use of the near-infrared spectrophotometric range analyses. They are currently proving useful in control of octane for gasoline production and blending processes, primarily because they capture the spectral nuances of chain branching fairly well. Chain branching has a strong link to preignition tendencies (octane) in a naphtha fuel. The technology, by itself, has been successful for other analyses, too. Dr Baughman's article **Near-infrared Spectroscopy in Analysis of Crudes and Transportation Fuels** will elaborate in this still-developing technology.

Finally, **Nuclear Magnetic Resonance Characterization of Petroleum** by Dr F.P. Miknis provides a detailed overview of this old but sophisicated technology as applied to petroleum hydrocarbons.

If the reader is curious about any analysis methodology, several articles in general are available in this encyclopedia and the instrument vendors will always be willing to supply information that may be of use.

On the theory that old is not necessarily bad, this Section Editor has composed a piece involving the utilization of the more classical petroleum analysis methods. As Dr Nero states so well in his Introduction, ''Generally accepted industrials analytical procedures do not adequately define chemical composition of various petroleum products and mixtures, but these methods provide little or no information concerning specific chemical components. These industrial procedures only determine the overall physical or chemical characteristics of a petroleum product, which are necessary to market the product. Physical properties such as boiling range, density, viscosity, flash point and vapor pressures are determined. General chemical characteristics such as carbon, hydrogen, and nitrogen content, total sulfur, average molecular weight, octane number and cetane number are also determined''.

The Editor heartily agrees but these are precisely the values that commercial petroleum refiners, particularly for fuel production facilities, are most concerned about right now. They control their processes to these items and must meet certain product specifications, again involving these same quantities. The amount of quality historical data available for estimation and cross-correlation of these properties is impressive and is still being added to. Since these procedures will not die soon, we decided to discuss them for some measure of topical completeness.

Having covered some of the more important analytical techniques necessary for ''adequate'' characterization, our remaining articles cover the specific analytical needs of various feed and product streams themselves.

Two articles deal with the analysis of full-range crudes. Dr M.A. Ali's contribution, **Full Range Crudes, Analytical Methodology of**, covers the spectrum of classical and the latest methodologies for characterizing and speciating broad boiling range hydrocarbons. The article entitled **High-temperature Simulated Distillation Applications in Petroleum Characterization** by D.C. Villalanti et al. describes one of the most important tools for such analyses. (O.K., if you are a purist, this article might better have been grouped with those mentioned above but

it is an increasingly utilized technique in crude oil assay methods.)

Dr C.S. Hsu's contribution, **Diesel Fuels Analysis** describes physical properties and chemical composition of diesel fuels. It addresses various issues including performance, storage stability, evaluation of refinery process efficiency and product quality, and assessment of environmental impact. Various methods of physical property measurement, performance tests, contaminant analyses, and analytical techniques for chemical composition are described.

The Editor has reprised and updated an earlier Wiley encyclopedia covering similar analytical considerations required for satisfying mandated regulatory analysis of transportation fuels. With the main emphasis of this latter article being on light naphtha (gasoline) stocks, the previous article provides a good balance for our coverage of transport fuels. It was somewhat difficult to be authoritative on actual requirements since little new legislation has been formally enacted since the mid-1990s. Many refiners are just now gearing up to meet these fiats. Much is currently being discussed, however, and we try to treat these ''suggestions'' as what probably will be the driving legislation to come within the next few years, perhaps even by the time this volume is published.

Dr Stanley Sandler is a world-renowned thermodynamicist and his discussion of oxygenate vapor–liquid equilibrium analysis, **Oxygenate Vapor–Liquid Equilibrium in Gasolines**, could not be adequately covered in any other way but directly from the source himself. In his article, he reviews the equipment and measurement methods commonly used to study the vapor–liquid equilibrium of hydrocarbon–oxygenate and gasoline–oxygenate mixtures. Detailed tables indicate those oxygenate–hydrocarbon mixtures for which vapor–liquid equilibrium data are available.

Dr W.K. Robbins' **Metals, Nitrogen and Sulfur in Petroleum Residue, Analysis of** considers contaminants in the residual fraction drawn off the bottom of towers or flash drums. These residues have an increased concentration of minor impurities, including sulfur-, nitrogen-, and oxygen-bearing heterocyclics, soluble nickel and vanadium compounds, and a variety of trace metals. These impurities both dominate the unique properties of the residue and play a major role in determining the refining processes necessary for its conversion to marketable products. This article introduces the common analytical techniques for the measurement of sulfur, nitrogen, nickel, vanadium, and trace metals in this challenging organic matrix.

Dr Bacaud's **Petroleum Residues, Characterization of** deals with the analytical classification of speciation types and prediction of properties of residue streams in general. Distinctions are drawn between atmospheric and vacuum residues. Since the simplest, lighter constituents of petroleum have been separated by distillation, residues concentrate the most complex fraction of crude oil and a detailed inventory of the individual compounds is impossible. Thus characterization methods will aim at giving an adequate description of the types of compounds contained therein.

A lubricant is a substance that reduces friction and wear between surfaces. Base oils typically comprise 80–99% of the finished lubricant. They are refined from selected crude oils, re-refined from used oil, synthesized from specific organic compounds, or extracted from renewable resources, such as seed oils. Base oils formulated into finished lubricants help to reduce friction and wear between moving surfaces, remove heat, seal, cushion against shock loads, and remove abrasives and contaminants from the lubricated area. Because of the special handling and processing required for lubricant stocks, we have three articles dealing with their analysis and characterization.

Dr Shugarman's article, **Lubricant Base Oils: Analysis and Characterization of**, is concerned with the lubricant base oils, or base stock. These stocks are combined with performance additives to make finished industrial and automotive lubricants. Base oil analysis and characterization is important for understanding how the physical and chemical properties of these materials relate to performance in finished lubricants. It is also essential for maintaining quality control over the manufacturing process, quality assurance of the finished product, and for setting specifications between buyer and seller.

Lube Products. Molecular Characterization of Base Oils, by Dr Montanari, covers the other end of lube technology. Finished oil considerations include final product specifications which are nearly as varied as those of transport fuel. The author shares some of his career's work in this area.

Dr J.G. Groetsch has written **Refractive Index Technology as a Real Time Viscosity Technique**, which describes the use of an online digital process refractometer to determine the viscosity index of lube oil stocks. Since lube oils are Newtonian fluids, refractive index can be related to viscosity index. Real-time continuous measurement of the lube stock refractive index has eliminated sampling, improved product consistency, reduced waste, and helped to optimize the process.

Oil shale is an alternative source of liquid hydrocarbons. The organic matter in an oil shale is mostly in the form of kerogen, which is defined as that fraction of the organic matter in a sedimentary rock that is insoluble in common petroleum solvents. The insolubility of kerogen is the main reason why an oil shale must be heated to produce liquid products. As with petroleum, standard assays do not provide information

about what chemical properties of oil shales are important for producing liquids. Consequently, a number of alternative procedures have been developed to analyze oil shales. These procedures, along with methods of analyzing shale oils, are described in the article **Oil Shale and Shale Oil Analysis**. The Editor feels that most of these techniques would be appropriate, along with aromatics analysis techniques presented elsewhere in this volume, for the characterization of coal-derived liquid hydrocarbons.

With that, we have covered pretty much the whole range of hydrocarbons. Some of these methods work well for any multicomponent organic liquid but this is something for you the reader to decide. We hope we have been able to present the current state of hydrocarbon analysis in its many flavors.

Diesel fuels are analyzed for their physical properties and chemical composition to address various issues including their performance, storage stability, evaluation of refinery process efficiency and product quality, and assessment of environmental impact. Various methods of physical property measurement, performance tests, contaminant analyses, and analytical techniques for chemical composition are described.

1 INTRODUCTION

Diesel fuels are the fuels used in diesel or compression ignition engines. In diesel engines, the air is compressed to high temperature before the fuel is injected into the cylinder to ignite or detonate. Compared to spark ignition engines, a diesel engine is cost effective because of its operating advantages, greater efficiency, high power output, and fuel economy under all loads. However, it has disadvantages of noise and emissions of particulates and nitrogen oxides (NO_x). Three grades of diesel fuels are in common use: (1) land diesel fuels, used in trucks, buses, trains, or other land transportation vehicles that have high variation of speed and load; (2) marine diesel fuels, used in ships that have variable speed but relatively high and uniform load; and (3) plant diesel fuels, used in electric power generation plants that have low or medium speed with heavy load. Hence, the quality of the diesel fuels depends on the performance requirements of the engines.

Today, the majority of diesel fuels are derived from petroleum, although some may come from other fossil fuel resources such as coal liquefaction fractions and through synthesis, such as Fischer–Tropsch distillates. The quality of diesel fuels can vary significantly owing to differences in the crude oils from which the fuels are derived and the refinery process streams from which they are blended. For example, there are significant differences in composition between straight run and hydrotreated cracked diesel streams. Diesel fuels taken from refinery streams for land transportation are the lightest and narrowest distillation cuts, while those for power plants are the heaviest and broadest cuts (fuel oils). The plant diesel fuels also contain the highest concentrations of sulfur and other heteroatoms.

The main sources of diesel fuels from refinery streams are straight run middle distillates from atmospheric and vacuum pipestills (distillation towers). Other streams that may be blended into the diesel pool include heavy cracker naphtha/oils and light coker oils. These streams are often hydrotreated to improve stability and to reduce sulfur and aromatics content. The most important properties of refinery streams for diesel blending include cetane number, initial boiling point (IBP), 95% boiling point, American Petroleum Institute (API) gravity (density), and viscosity. Cetane number is governed by industrial specifications. Among refinery streams that are blended into diesel pools, virgin middle

distillates and hydrocracker bottoms have the highest cetane number (35–60). Light catalytic cracker oil (LCCO) has the lowest cetane number (<20) and is generally blended with high cetane number streams to reach a cetane number >40 for land and marine (transportation) diesel fuels and >30 for plant (industrial) diesel fuels.

Diesel fuels are analyzed for their physical properties and chemical composition to address various issues including their performance (combustion efficiency), storage stability, evaluation of refining process efficiency and product quality, and assessment of environmental impact.

2 METHODS FOR PHYSICAL PROPERTIES MEASUREMENT

Physical properties of diesel fuels are measured to determine the ease of volatilization and flow in fuel lines and the storage stability of the fuels. The properties to be measured generally include boiling point, flash point, cloud point, pour point, density, viscosity, and color.

There are many established methods for measuring physical properties of diesel fuels. The American Society for Testing and Materials (ASTM) and the Institute of Petroleum (IP) have published standard methods for such measurements.[1,2] Some of the important tests that are generally included in fuel specifications are briefly discussed below.

2.1 Boiling Range

Boiling range (or distillation limits) is measured to ensure that fuel products have suitable volatility. The boiling range is defined as the temperatures between the IBP and the final boiling point (FBP). The temperature at which 95% of the fuel has evaporated (T95) is frequently specified. The boiling range of diesel fuels can be obtained by the low efficiency ASTM D 86 (IP 123) test method or by ASTM D 2892, which gives true boiling point measurements using a 15-theoretical plate column. However, both ASTM D 86 and D 2892 require a rather large volume of sample. Boiling range distributions (distillation curves) of diesel fuels have therefore been more conveniently determined using gas chromatography (GC), ASTM D 2887. This so-called ''GC simulated distillation'' method uses a GC column coated with nonpolar methyl silicone as a stationary phase. After calibration, the retention times of the components are essentially equivalent to the true boiling points determined by ASTM D 2892. The boiling range for typical land transportation diesel fuels is between 350 °F (177 °C) and 650 °F (343 °C), although for some diesel fuels the IBP and/or FBP are slightly out of this range.

2.2 Flash Point

Flash point is used to determine the temperature at which the vapor space above the fuel can be ignited by a spark or other ignition source. The flash point of a diesel fuel can be determined by ASTM D 93 (IP 34) using a Pensky–Martens closed cup tester or by ASTM D 56 using a Tag closed tester. In the test, the sample is placed in a cup of the tester with the lid closed. The lowest temperature at which a small flame of a specified size causes the vapor above the sample to ignite is recorded as the flash point. Flash points of transportation diesel fuels are generally >40 °C. Fuel oils used for low- and medium-speed engines have a minimum flash point of 55 °C.

2.3 Low-temperature Flow Characteristics

Either ASTM D 2500 (IP 219) or D 3117 test can be used to determine the temperature at which a cloud of wax crystals first appears in fuel when it is cooled. The temperature is recorded as cloud point. The cloud point of a diesel fuel is typically +10 to −40 °C.

The lowest temperature at which a fuel stays fluid is recorded as its pour point, as determined by ASTM D 97 (IP 15). A typical diesel fuel has a pour point between −10 and −40 °C.

There are a number of filterability tests. In some cases they supplement the measurements of pour point and cloud point, and are particularly useful for evaluating fuels containing flow improver additives. In the ASTM D 4539 test, the temperature of the test fuel is lowered at a controlled cooling rate. The lowest temperature at which a fixed volume of the fuel can be filtered through a specific mesh (17 μm) of screen in less than a given period of time (60 s) is recorded as minimum low-temperature flow test (LTFT) pass temperature. In Europe, the standard test method for cold-flow performance of diesel fuels is the cold filter plugging point (CFPP), designated as EN116 (identical with IP 309).[2,3] CFPP is the highest temperature at which a given volume of fuel fails to pass through a standardized wire mesh filter under a controlled vacuum in a specified time, when cooled under standardized conditions.

Cloud point, LTFT, and CFPP are measured for vehicle operability. Pour point is for fuel distribution system in the vehicle.

2.4 Density/Relative Density (or American Petroleum Institute Gravity)

There are two standard methods adopted by ASTM for density measurement. The D 1298 (IP 160) method uses

a hydrometer that is immersed in a test fuel at a specific temperature, and the D 4052 (IP 365) method uses a digital analyzer consisting of a U-shaped, oscillating sample tube and a system for electronic excitation, frequency counting, and display. The relative density (specific gravity) at 60 °F can also be represented by API gravity.

$$\text{API gravity, deg} = \frac{141.5}{\text{specific gravity at } 60\,^{\circ}\text{F}} - 131.5$$

Typical densities of transportation diesel fuels at 15 °C (60 °F) are 0.80–0.86 g mL^{-1}, or 33–45° API gravity.

2.5 Viscosity

The kinematic viscosity of diesel fuels is important to their effective use, e.g. for flow of fuels through fuel lines, injection nozzles, and orifices. In the ASTM D 445 (IP 71) test, a fixed volume of fuel flows through a calibrated viscometer under a reproducible driving head and at a closely controlled temperature. The kinematic viscosity is the product of measured flow time and the calibration constant of the visocometer. Dynamic viscosity is obtained by multiplying the measured kinematic viscosity by the density of the fuel. The kinematic viscosity range of transportation diesel fuels at 40 °C is 1.3–4.1 centistokes (cSt or $mm^2\,s^{-1}$) with most being between 1.9 and 4.1 cSt. The kinematic viscosity of fuels used in heavy-duty low-speed engines is in the range 5.5–24 cSt.

2.6 Aniline Point

Aniline point is not generally used any more for estimating the aromatics content of a fuel. To determine the aniline point, a specific volume of aniline is mixed with the fuel, as in the ASTM D 611 (IP 2) test method. The mixture is cooled at a controlled rate. The temperature at which two phases separate is recorded as the aniline point. Aniline points are high for paraffins and low for aromatics with cycloparaffins and olefins in between. The aniline point has been found to be highly correlated with the cetane number of diesel fuels.

2.7 Color

Color is used as an indication of fuel quality. A variation outside the established range may indicate degradation or contamination of the fuel with other products. It is not, however, a reliable predictor of stability. A scale ranging from 0.5 to 8.0 is used in the ASTM D 1500 (or IP 196) test, which employs a standard light source and a comparison of colored glass disks.

3 PERFORMANCE TESTS

One of the most important tests for diesel fuel performance is cetane number, a measurement of the ignition quality of fuels in a diesel engine. For usage and storage, standard tests for heating value, lubricity, filterability, corrosivity, and oxidation stability of the fuel have also been established.

3.1 Cetane Number

The cetane number of a fuel is measured on a single-cylinder rating engine by comparing the fuel performance with blends of *n*-hexadecane and α-methylnaphthalene or heptamethylnonane. A diesel fuel with cetane number 55, for example, matches the performance of a blend of 55% of *n*-hexadecane and 45% of α-methylnaphthalene in the cetane engine.

Methylene groups (CH_2) not incorporated in naphthenic rings and more than three carbon atoms from any other structures (such as aromatic rings, methyl groups, double bonds, or naphthenic rings) are the single most important molecular features for cetane number. The molecules with highest cetane number are the straight-chain normal paraffins. The molecules with lowest cetane number are those having few methylene groups. The presence of double bonds in molecules will lower the cetane number. Hence, the general trend of cetane number among the molecular types is *n*-paraffins > isoparaffins > cycloparaffins > aromatics. Within a homologous series, for example the paraffins, the cetane number increases with molecular weight.

Typical cetane number ranges of refinery process streams are: virgin distillate streams–light (jet), 35–46, mid (diesel), 35–60, heavy (light virgin gas oil), 46–56; LCCO, 14; heavy coker naphtha (HKN), 37; light coke gas oil (LKGO), 40–45; and hydrocracker fractionator bottoms, 42–58. These streams may be blended into diesel fuel pools.

3.2 Cetane Index

Various correlations between cetane number and other measured properties are in use. Frequently these correlations are proprietary or limited to restricted groups of diesel fuels. For the determination of cetane number, an engine performance test uses a large volume of fuel over a rather long period of time. In addition, the engine requires extensive and continuous maintenance to assure the quality of cetane ratings. Hence, ASTM has developed two cetane indices that refineries generally use for estimating the cetane number of diesel fuels. In ASTM D 976 (IP 264), the cetane index is calculated from API gravity and ASTM D 86 mid boiling point (T50). An

alternative method for estimating cetane number of a transportation diesel fuel is the ASTM D 4737 (IP 380), a four-variable method that uses density and 10% (T10), 50% (T50), and 90% (T90) recovery temperatures of the fuel as variables.

Cetane index does not reflect the use of cetane improver, but correlates with the aromatics of the fuel.

3.3 Heating Value

The heating value or energy content of diesel fuel affects fuel economy and power output. Standard methods for heating value measurement include ASTM D 4809 for transportation diesel fuels and ASTM D 4868 for plant diesel fuels. Typical heating value for land diesel fuels is 134 000 Btu gal^{-1} (or 19 700 Btu lb^{-1}); for marine diesel fuels, 138 000 Btu gal^{-1}; and for plant diesel fuels, 148 000 Btu gal^{-1}.

3.4 Lubricity

Lubricity of diesel fuel can affect the life of engine components such as fuel injection pumps. There are many methods for evaluating diesel lubricity. ASTM has standardized two methods: high-frequency reciprocating rig (HFRR) as ASTM D 6079 and scuffing load ball on cylinder lubricity evaluator (SBOCLE) as ASTM D 6078. The HFRR method has also been standardized by ISO (International Organization for Standardization) as CEC F-06-A-96. No absolute correlation has been developed between these two methods or between these methods and field performance.

In the ASTM D 6079 (HFRR) test, a fixed volume of the fuel is placed in the test reservoir. During the test, a vibrator holding a nonrotating steel ball loaded with a specified mass (e.g. 200 g) is lowered to contact a disk that is completely submerged in the fuel. At a specific test temperature, the ball rubs against the disk with a 1-mm stroke at a frequency of 50 Hz for 75 min. The wear scars on the ball are measured under a microscope with a 100 × magnification. Typical results are 250 (good) and 600 (bad) μm. The target is currently set at <460 μm.

In the ASTM D 6078 SBOCLE test, a load arm holding a nonrotating chrome alloy steel ball is lowered to contact a partially fuel-immersed polished steel test ring rotating at a specific speed (e.g. 525 rpm). The ball rubs against the test ring for a given period of time, and the tangential friction force is recorded. Tests can be performed with a single load or incremental load following prescribed procedures. Typical incremental load results are 2500 to 5000 g, with >3100 g considered as good lubricity.

3.5 Corrosivity

The corrosivity of diesel fuels can be measured by the ASTM D 130, jointly with IP 154, copper strip tarnish test. A polished copper strip is immersed in a given quantity of fuel sample and heated at a specific temperature for a given amount of time. The copper strip used in the test is then compared with an ASTM Copper Strip Corrosion Standard to classify the corrosivity of the fuel.

3.6 Stability

The stability and the quantity of insoluble material formed during storage of diesel fuels under air over a given period of time can be tested by ASTM D 4625 (or IP 378). In this test, fixed volumes (400 mL) of filtered fuel are aged in borosilicate glass containers at 43 °C for periods of 0, 4, 8, 12, 18, and 24 weeks. After aging for a selected time period, the total amount of filterable and adhesive insolubles is measured after a sample is removed from storage and cooled to room temperature. This method is not suitable for quality control testing because of long storage periods, but it can be used as a tool for studies of fuel storage properties.

There are two accelerated oxidation tests adopted by ASTM. In the method of D 2274, a fixed volume of fuel is bubbled with oxygen at a specific rate and temperature for a given period of time. The total amounts of filterable and adhesive insolubles formed during the test are measured as mg per 100 mL. The second acceleration test, ASTM D 5304, uses an oxygen overpressure. In this test, 100 mL of fuel, with or without stabilizer additives, is placed in a borosilicate container that is then placed in a pressure vessel preheated at 90 °C. The vessel is then pressurized with oxygen to 100 psig (pounds per square inch) (800 kPa) and placed in a forced air oven at 90 °C for 16 h. The sample is cooled at the end of test to determine gravimetrically the amount of fuel insolubles. This method achieves acceleration of oxidation without resorting to higher temperatures.

A thermal stability test method of diesel fuels is under development in ASTM, which is based on Octel/Dupont F21-61 Accelerated Fuel Oil Stability test. In this test, 50 mL of fuel is passed through a 200-mesh filter at 150 °C for 90 or 180 min. The reflectivity of the filter under a standardized light is measured to determine the thermal stability of the fuel.

4 ANALYSES OF FUEL CONTAMINANTS

Water and ash contents are contaminants in diesel fuels. They are measured to meet specifications that are agreed upon between purchasers and suppliers at the time and place of delivery.

4.1 Water and Sediment

Water and sediment in diesel fuel can cause increased corrosion, filter plugging, and engine damage. In ASTM D 1796 (IP 75), a mixture of equal volumes of fuel and water-saturated toluene is centrifuged, after which the volumes of the water and sediment layers are read.

4.2 Ash Content

The amount of ash-forming material in diesel fuel is measured to determine whether the fuel might have unacceptable deposits on combustion. Ash can come from oil- or water-soluble metallic compounds or from extraneous solids such as dirt and rust. In the standard ASTM D 482 (IP 4) test, a weighed sample is burned in a vessel until ash and carbon remain. The carbonaceous residue is then placed in a muffle furnace at 775 °C to reduce it to a carbon-free ash; it is weighed after it has cooled to room temperature.

4.3 Carbon Residue

The carbon residue of base fuel without additives can indicate the coke-forming propensity of the fuel when used in pot-type and sleeve-type burners. In the ASTM D 524 (IP 14) test, a weighed sample is placed in a glass bulb with a capillary opening; the bulb is heated in a metal furnace at 550 °C. After volatile matter has evaporated, a small amount of air is introduced into the bulb for slight oxidation. The residue remaining in the bulb is reported, as a percentage of the original sample, as the Ramsbottom carbon residue.

5 ANALYTICAL TECHNIQUES FOR CHEMICAL COMPOSITION

Diesel fuels are mainly composed of hydrocarbons, with minor or trace amounts of sulfur-, nitrogen-, and oxygen-containing compounds. The determination of chemical composition of diesel fuels involves both standard tests and nonstandard instrumental analysis.[4]

5.1 Elemental Analysis

In addition to carbon and hydrogen, diesel fuels contain trace amounts of sulfur, nitrogen, oxygen, and other elements. The hydrogen-to-carbon ratio can be used to assess fuel characteristics and refining process performance. Sulfur and nitrogen contents are environmental concerns. Like the hydrogen-to-carbon ratio, they can also be used to assess the efficiency of upgrading processes at refineries. Carbon, hydrogen, and nitrogen contents (CHN analysis) can be simultaneously determined using instruments, as described in ASTM D 5291. In this method, the sample is combusted at 950–1020 °C. The combustion product is passed through calcium oxide to remove sulfur oxides. The remaining combustion gas is then passed over a heated copper train to remove excess oxygen and reduce nitrogen oxides (NO_x) to N_2. The final gas mixture of N_2, CO_2, and H_2O is separated by a heated gas chromatographic column and measured by a thermal conductivity detector. Alternatively, the gas mixture is passed over NaOH to remove CO_2 and then over magnesium perchlorate to remove H_2O. A thermal conductivity cell measures the remaining N_2. Simultaneously, but separately from the nitrogen measurement, the carbon and hydrogen are determined by measuring the CO_2 and H_2O levels using infrared (IR) cells.

There are several standard methods for the sulfur measurement. In a combustion method for samples with >0.1% sulfur (ASTM D 129), the sample is combusted in a closed bomb containing oxygen. The sulfur content is determined by weighing barium sulfate in the bomb washings after reaction with a known amount of barium chloride solution. Another method adopted by ASTM, D 1552, is to combust the samples that contain at least 0.06% sulfur in a stream of oxygen. The combustion product is continuously absorbed in an acidic solution of potassium iodide with starch indicator. Potassium iodate is added to the absorber solution to maintain the solution as a slightly blue color. The amount of potassium iodate consumed during combustion is used to determine the sulfur content.

The sulfur content can also be determined by instrumental methods. For samples containing 0.05 to 0.5 mass% sulfur, ASTM D 4294, using energy dispersive X-ray fluorescence (EDXRF) spectroscopy, can be employed. For samples with less sulfur, ASTM D 2622, a method that is based on the measurement of the Kα line at 5.373 Å ($1\ \text{Å} = 10^{-10}$ m) by wavelength-dispersive X-ray spectrometry after background subtraction, can be used. However, care should be taken to avoid or to correct for interference from other elements as impurities in the sample.

The oxygen content of the fuel is usually of little concern. It can be obtained by taking the balance of the CHNS analysis, i.e. 100% minus the percentages of the four elements. More accurate measurement can be obtained by neutron activation analysis (NAA), in which the sample is bombarded by high-energy (~14 MeV) neutrons. The intensity of the γ-rays emitted from the nuclei at a known time after the sample has been neutron irradiated is measured to determine the concentration of the element.

5.2 Chromatography

Diesel fuels can be separated by chromatography according to polarity and boiling point. Polarity separation is

normally carried out in liquid phase by liquid chromatography (LC), while boiling point separation is carried out in gas phase by GC. In general, liquid-phase separation has low resolving power that can separate components only into compound type groupings. High resolving power to resolve individual components is achievable with gas-phase separation. However, because of the large numbers of components present in diesel fuels, co-elution of components is common even with high-resolution GC using capillary columns.

5.2.1 Liquid Chromatography

Several standard liquid chromatographic methods have been established for diesel analysis. A simple test for determining the concentrations of aromatics and olefins in diesel fuels uses a fluorescent indicator adsorption (FIA) method, ASTM D 1319. The sample is introduced into a glass adsorption column packed with activated silica gel, with a small layer of the gel containing a mixture of fluorescent dyes. After all the sample is adsorbed onto the gel, alcohol is added to desorb the sample down the column. Aromatic, olefinic, and saturated hydrocarbons are separated according to their affinity with the gel. The dyes are also separated with hydrocarbon types. The boundaries of different hydrocarbon zones can be made visible under ultraviolet light. The volume percentages of aromatics, olefins, and saturates are calculated from the length of the zones.

A standard high-performance liquid chromatography (HPLC) method, IP 391, has been adopted by the European Community. It utilizes a polar column and refractive index detection to measure the amounts of saturates (nonaromatic hydrocarbons) and mono-, di-, and polynuclear aromatic hydrocarbons.[2] In this method, a known mass of the sample is diluted in a nonpolar solvent, such as heptane, and a fixed volume of the solution is injected into a HPLC set-up with a polar column (normal phase HPLC) to separate components according to aromatic ring types. Nonaromatic hydrocarbons that have little affinity with the column elute first, followed by mono- and diaromatic hydrocarbons. Then, the column is backflushed to elute the polynuclear aromatic hydrocarbons as a single peak. The column temperature is maintained constant ($\pm 1\,^{\circ}C$) within the range 20–40 °C. However, the responses of the refractive index detector to hydrocarbon molecules depend on the structure, and they vary greatly with different types of molecules. Hence, careful calibration in response factors is necessary to ensure accuracy of the quantitative measurement. Photodiode array (PDA) detection can be used for distinguishing and identifying the aromatic type of the components. However, its use for quantitation is also limited by nonuniform responses for various types of aromatic hydrocarbons.

5.2.2 Supercritical Fluid Chromatography

Supercritical fluid chromatography (SFC) with flame ionization detection (FID) has proven to be quite effective for the determination of the total amount of aromatics in diesel fuels.[5,6] It has become a standard ASTM method (ASTM D 5196) for the determination of aromatic content and polynuclear aromatic content of diesel fuel. A small volume of the sample is injected onto a packed silica column and eluted using supercritical carbon dioxide as the mobile phase. Monoaromatic and polynuclear aromatic hydrocarbons are separated from nonaromatic hydrocarbons (saturates and mono-olefins, if present). The resolution among different aromatic types is poor, especially for the distinction between di- and triaromatics. However, the relatively uniform response of FID for different hydrocarbon types is an advantage of this method.

A more elaborate SFC separation scheme has been suggested by Andersson et al.[7] It uses multiple columns and supercritical carbon dioxide as a mobile phase to determine saturated compounds (paraffins and naphthenes), olefins, mono-, di-, and triaromatics, and polar compounds in diesel fuel distillates. Using a valve switching technique, compounds are retained and then eluted from the multiple columns at different times. During the compound retention period, polar compounds are retained in a cyano-bonded column, aromatics in a silica column, and paraffins and olefins in a silver-impregnated column. During the elution period, aromatics are eluted from the silica column first, after which the polars are back-flushed from the cyano-bonded column. Saturates are then eluted from the silver-impregnated column, followed by back-flushing the olefins from the silver-impregnated column. A mass spectrometer coupled with SFC is used to provide the basis of column switching, to select integration limits, and to obtain more detailed distributions of compound types.

5.2.3 Gas Chromatography

GC has been used for routine analysis of volatile complex organic mixtures. Although many different stationary phases can be used, the most common columns in GC analysis are coated with nonpolar methyl silicone. With a nonpolar GC column, components are separated essentially by boiling point. This correlation between boiling point and GC retention time is the basis for using GC simulated distillation, described earlier, to estimate yields of petroleum distillates, including diesel fuel streams. For general quantification, FID is used because of its uniform response across various hydrocarbon types.

GC with element-specific detectors can conveniently measure small or trace amounts of sulfur- and nitrogen-containing components in diesel fuels. Specific detection is important not only in quantifying trace amounts of

heteroatom-containing compounds without interference from the overwhelming hydrocarbon components, but also in helping combined gas chromatography/mass spectrometry (GC/MS) to focus on retention time regions in identifying heterocompounds of interest.

Atomic emission detectors (AED) can simultaneously detect several elements including C, H, N, S, and O.[8] The GC effluent is introduced into a microwave plasma cavity where the compounds are atomized and excited by plasma energy. The light emitted from the excited atoms is separated by PDA and sorted by computer to produce chromatograms specific to individual elements. Another specific detection is based on chemiluminescence to detect light emitted from chemical reactions. Unlike AED, in which the light comes from excited atoms, the light in chemiluminescence comes from excited molecules produced by reaction with a strong oxidizing agent such as ozone. Sulfur and nitrogen compounds can be detected using chemiluminescence as a means of specific detection.[9] Other sulfur- and nitrogen-specific detectors include flame photometric detectors (FPD)[10] and nitrogen/phosphorus detectors (NPD),[11] respectively. Oxygen compounds can also be detected by oxygen-selective flame ionization detectors (OFID).[1] The oxygenates are cracked by flowing the GC effluent through a capillary tube containing Pt/Rh catalysts at 850–1300 °C to form carbon monoxide, which is then converted into methane as it flows through a hydrogenator following the cracker. A flame ionization detector detects the resulting methane.

5.3 Mass Spectrometry

Mass spectrometry alone has also been used for hydrocarbon type analysis of diesel fuels and other middle distillates.[12] The concept of hydrocarbon type analysis is to use mass spectral fragment peak summations, each respectively characteristic of compound types to be determined.[13] Numerous components are grouped into a few compound types as paraffins, cycloparaffins, monoaromatics, diaromatics, polynuclear aromatics (3+-ring aromatics), and sulfur compounds. Sulfur compounds (benzothiophenes, dibenzothiophenes, and benzonaphthothiophenes) are the only heteroatom-containing compound types included in the analysis. These are the major compound types typically found in diesel fuels. Due to overlaps of mass series of certain saturated and aromatic hydrocarbons, the sample is preferably separated by elution chromatography, e.g. modified ASTM D 2549, into saturate and aromatic fractions before the mass spectrometric analysis. The separated fractions are analyzed by mass spectrometry using ASTM D 2425 for both or ASTM D 2786 for saturates and ASTM D 3239 for aromatics.[1]

The most detailed compositional analysis of diesel fuels can be obtained by GC/MS, in which a gas chromatograph separates components before their elution into a mass spectrometer for characterization. However, because of the numerous components in diesel fuels, complete or near-complete separation of individual components by GC is impossible. Hence, for trace components, open column, HPLC or other types of chemical separations are often used to concentrate components of interest (typically heteroatom-containing compounds) for GC/MS analysis with minimal interference from the predominant components.[14]

For further analysis, relatively pure fractions can be obtained by chromatographic procedures that fractionate the sample into saturates, monoaromatics, diaromatics, polyaromatics, and nitrogen/oxygen compounds (polars). Each fraction can then be characterized by GC/MS for the identification of isomers. Many of these fractions can be further separated by thermal diffusion for greater enrichment of various subtypes, i.e. paraffins, alkylbenzenes, naphthalenes, etc.

The carcinogenic, teratogenic, and/or mutagenic activities of polycyclic aromatic hydrocarbons (PAHs) are isomer specific. Diesel fuel can be separated by solid phase extraction into saturates, mono-, di-, and polyaromatic hydrocarbons. The 2- and 3-ring aromatics are identified by capillary GC and GC/MS.[15]

5.4 Nuclear Magnetic Resonance and Molecular Spectroscopies

Unlike chromatography and mass spectrometry, which can analyze components at a molecular level in a complex mixture, nuclear magnetic resonance (NMR) and molecular (IR and Raman) spectroscopies are used to determine the average structure of a mixture. However, the specific chemical shifts of functional groups in NMR and their unique vibrational frequencies in IR and Raman spectroscopies provide valuable information about their distribution in the mixture. For example, ^{13}C-NMR has been used to effectively determine the content of aromatic and aliphatic carbons in diesel fuels.[16]

6 MOLECULAR COMPOSITION OF DIESEL FUELS

Analysis of a representative diesel fuel by the methods described here shows that the main components of diesel fuels are saturated and aromatic hydrocarbons. The saturated hydrocarbons dominant in diesel fuels include normal paraffins, isoparaffins, and cycloparaffins (naphthenes). Normal paraffins have high cetane numbers and are desirable molecules in diesel fuels

for combustion. High-boiling normal paraffins, however, cause cold-flow problems if present in excess. Other than isoprenoid hydrocarbons such as pristane and phytane, most of the isoparaffins in diesel fuels are mono- and dimethyl alkanes, predominantly with branch points near the ends of the alkyl backbone. The remaining saturated hydrocarbons are mainly 1-ring to 3-ring cycloparaffins. The 4- and 5-ring cycloparaffins, such as steranes and hopanes, are rarely present. Aromatic compounds are mainly benzenes, indans, tetralins, indenes, naphthalenes, biphenyls, acenaphthenes, fluorenes, acenaphthalenes, phenanthrenes, anthracenes, and naphthenophenanthrenes. Diaromatic hydrocarbons are generally the most abundant aromatic components in diesel fuels. Trace amounts of PAHs (3+-ring aromatic compounds) such as chrysenes, pyrenes, benzanthracenes, and perylenes can also be present.

The most common sulfur compounds are benzothiophenes and dibenzothiophenes. Trace amounts of nitrogen compounds include indoles, carbazoles, quinolines, acridines, and phenanthridines. The oxygen compounds most often reported in diesel fuels are phenols and dibenzofurans.

Formulated diesel fuels also contain small amounts of additives, such as cetane improvers, antioxidants, corrosion inhibitors, metal deactivators, dispersants, detergents, lubricity agents, demulsifiers, and cold-flow improvers, to improve storage stability and performance.

Many physical and physico-chemical properties of diesel fuel are related to its composition. Linear regression and principal component analysis have been used for statistical analysis and correlation studies of chemical composition and physical characteristics (including cetane number and cetane index) of diesel fuels.[16–18]

The release of the Clean Air Act (CAA) Amendments of 1990 introduced reformulated gasoline legislation regulating the composition of fuels and particularly gasoline in order to improve the air quality by a significant reduction in vehicle exhaust emission levels. With the introduction of certain amounts of nonfuel oxygenates into fuel including various alcohols such as methanol, ethanol, t*-butanol and ethers like methyl* tert*-butyl ether (MTBE), ethyl* tert*-butyl ether (ETBE),* tert*-amyl methyl ether (TAME) and diisopropyl ether (DIPE) a reduction of carbon monoxide (CO) and unburned hydrocarbon emissions is envisaged. Furthermore, a reduction in aromatic compounds and benzene is demanded providing a decreased release of volatile organic compounds (VOCs).*

With the implementation of this program, the refining industry and their petrochemical laboratories have been forced to control accurately and to monitor continuously their gasoline blending processes. Furthermore, regulatory agencies are required to implement the use of portable analytical techniques in order to ensure the enforcement of such novel threshold values.

Besides the conventional techniques using separation-based methods such as gas chromatography (GC), the mid-infrared (MIR) spectral range has gained significant importance. Owing to the molecule specific absorption patterns of ethers, alcohols and aromatics, the distinct determination of fuel additives and subsequent derivation of general fuel parameters is enabled. The performance of FTIR (Fourier transform infrared) and filter-based spectroscopic techniques will be reviewed and compared to other spectroscopic approaches. Furthermore, data evaluation procedures and ASTM (American Society for Testing and Materials) approval of these novel methods will be highlighted.

1 INTRODUCTION

The improvement of the air quality by reduction of emissive pollution has been a major concern of environmental protection efforts in the 1990s. Since gasoline and diesel fuels together power more than 95% of the vehicle fleet in the USA, exhaust vehicle emissions, resulting from combustion products and contributing to the greenhouse effect as well as to the ozone problem, are considered a target issue.

With the release of the CAA Amendments of 1990, reformulated gasoline legislation was introduced, regulating the composition of fuels and particularly gasoline in order to improve the air quality by a significant reduction of vehicle exhaust emission levels.[1] In accordance with the act, the refining industry and their petrochemical laboratories are required to control accurately and to monitor continuously their gasoline blending processes. Added oxygenates include alcohols such as methanol, ethanol, *tert*-butanol and ethers like MTBE, ETBE, TAME and DIPE, which progressively reduce carbon monoxide (CO) and unburned hydrocarbon emissions with increasing oxygen content. Furthermore, the CAA enforces a reduction in content of aromatic compounds and benzene is reduced providing a decreased release of VOCs.

The standard determination method for such compounds is given in detail in section 2 and is based on gas chromatography with oxygen-selective flame ionization detection (GC/O-FID) as mandated by ASTM and USEPA (United States Environmental Protection Agency).[2,3] The increasing demand claimed by regulatory agencies as well as petroleum companies for rapid and reliable analytical techniques capable of assessing these parameters in the field, has initiated the search for novel methods to supplement and possibly replace conventionally used separation techniques.

Infrared (IR) spectroscopy and particularly the MIR spectral range considered from 4000 to 400 cm^{-1} (2.5–25 μm) represents an analytical technique of constantly increasing importance. The introduction of rapid and powerful microprocessors enabling the implementation of fast Fourier transform calculation algorithms, especially, have established FTIR spectroscopy as one of the most commonly applied analytical methods since the late 1970s.[4] While chromatographic techniques rely on the separation of the analyte molecules in the column in relation to their mass differences, IR spectroscopy enables the selective recognition of different species in relation to their specific molecular vibrations resulting in distinctive absorption bands in the corresponding spectral region. In contrast to NIR (near infrared) methods, MIR spectroscopy provides access to the comparatively strong fundamental vibrational modes of organic molecules, and individual fuel components can be differentiated by their characteristic pattern of absorption bands. Hence, the advantages of IR absorption spectroscopy compared to chromatographic systems particularly for a field applicable analytical method are evident: (i) usually no preparation of the sample is required, (ii) the potential exists for continuous operation providing on-line and real-time information because (iii) no preparation of the instrument prior to the measurement or after the determination is necessary, (iv) full analysis in typically less than 5 min, (v) the measurement and data evaluation procedure can be fully automated (chemometric methods), (vi) no extra trained personnel are needed.

Based on these considerations, several studies have proven that MIR FTIR spectroscopy is a versatile, efficient and accurate analytical technique for the determination of fuel additives and the estimation of key gasoline properties.[5] Besides supporting the control and implementation of environmental regulations, an alternative tool for petroleum laboratories is provided, which could considerably increase the sample throughput, minimize the sample preparation and volume requirements and reduce the costs per sample compared to conventional analysis.

2 CONVENTIONAL FUEL PERFORMANCE SPECIFICATION

2.1 Fuel Parameters and Properties

With respect to regulatory measures, the most important parameters of fuels which have to be addressed for sufficient fuel specification are listed in Table 1. The particular substances of interest, which have to be measured selectively, are given in Table 2.

With the introduction of oxygenate additives for gasoline, a reduction of ambient CO by about 10% is envisaged. Reformulated gasoline will reduce VOCs and air toxics by approximately 15% requiring a content of at least 2 wt% oxygen and a maximum content of 1 wt% benzene.

Besides this positive environmental impact it is of major interest to investigate potential human health risks related to these new additives, especially MTBE as the most common representative of the oxygenates. Since MTBE is a widely used fuel blending component its environmental fate, especially in the aquatic groundwater phase, as well as its adverse human effects are currently the subject of intensive investigations with particular focus on long-term studies.[6]

2.2 United States Environmental Protection Agency Regulations

Gasoline and diesel fuel produced from petroleum (crude oil) power more than 95% of the combustion engine motored vehicle fleet in the USA. With the release

of the CAA in 1990, strategies to reduce and prevent air pollution caused by vehicle exhaust emissions have refocused to emphasize improvements in fuel properties and thus fuel composition, rather than relying mainly on engine/vehicle emission control such as catalytic converters. This initiative led to provisions forcing modifications in the content in gasoline of nonpetroleum additives and, correspondingly, more stringent emission standards for combustion engines.

The pollution reduction programs implemented by the USEPA within the clean air legislation can be condensed into two main sections:[3]

(i) Oxygenated fuels program: during the winter months from November 1 to March 1 gasolines sold in metropolitan areas defined as CO nonattainment zones have to contain at least 2.7% (w/w) oxygen.

(ii) Reformulated gasoline program: to reduce the ozone and smog levels gasolines available in nine extended city areas with most severe ozone pollution have to be reformulated in the first phase of this program, launched in the beginning of 1995, to an oxygen content of at least 2.0% (w/w). A reformulation of their contents of aromatics, benzene, heavy metals, sulfur and detergents is also included in the program.

With the implementation and compliance of these regulations, an increasing demand for the accurate determination of the oxygen content of fuels and for appropriate analytical techniques is obvious.

Currently applied standard methods for the determination of fuel components including oxygenates and aromatics mainly involve separation techniques such as GC/AED (atomic emission detection), GC/FID (flame ionization detection) and GC/MS (mass spectrometry).[7–9]

3 MID-INFRARED SPECTROSCOPY FOR THE DETERMINATION OF FUEL PERFORMANCE SPECIFICATIONS

3.1 Short Introduction to Mid-infrared Spectroscopy

The MIR spectral range is generally considered to be from 4000 cm^{-1} to 400 cm^{-1} corresponding to 2.5–25 μm. Probing fuels and fuel mixtures with MIR radiation enables individual components to be detected and differentiated by their specific absorption pattern in this spectral region. Because the vibrational motions of the molecules occur at distinctive frequencies depending on their atomic masses, their relative bond strengths and their neighboring atoms and bonds, functional group assignment enables individual components to be distinguished in a fuel sample. This unique set of frequencies is directly associated with the molecular structure of the respective component and is represented in the so-called MIR spectrum of the analyte. Since MIR spectroscopy is based on the evaluation of the fundamental resonances, usually well-defined, sharp and specific absorption bands are available. The amplitude of the molecular vibrations is related to the concentration of the molecule within the sample and is represented in the peak height of an absorption spectrum. Since similar molecular structures partially result in absorption peaks located at the same frequency, the whole spectrum has to be evaluated for accurate data analysis.

The usefulness of applying MIR spectroscopy for fuel characterization becomes particularly evident when relating chemical gasoline features to the respective components influencing those properties.[10–12] As an example, the octane number is strongly influenced by the aromatic hydrocarbon concentration: an increase in these components increases the octane number and simultaneously decreases the cetane number for diesel fuels. As detailed later, aromatic components such as benzene can be detected directly in the MIR region. The investigation of so-called *oxygenated* fuels especially is facilitated using MIR spectroscopic methods.[13] Oxygen-containing fuel additives – mainly alcohols and ethers – improve the performance of combustion engines towards a more complete burning process thus reducing the CO emissions of vehicles by 15–20%. Because the characteristic C–O–H bonds of alcohols and the C–O–C bonds of ethers are represented by distinct absorption bands in the MIR region, analytical tools operating in that particular spectral region are of significant interest.

Examples of IR spectra of fuel additives are given in Figure 1 and demonstrate the suitability of detecting individual components using MIR spectroscopy as well as revealing the difficulty of differentiating between individual substances within a complex mixture.

Generally, the reported instrumentation can be divided into (i) FTIR spectrometer-based instruments that evaluate the whole spectral range using either attenuated total reflection (ATR) or micropath transmission cells, (ii) filter instruments that use a set of bandpass filters and a chopped light source to evaluate only the MIR spectral region of interest and (iii) hyphenated techniques that combine MIR spectroscopic detection with GC.

The most important techniques based on MIR spectroscopy, which can be applied to determine fuel specifications, are discussed below.

3.2 Fourier Transform Infrared-based Instrumentation

Various studies have shown that FTIR spectroscopy in the MIR region is the most versatile, efficient and accurate spectroscopic technique for the simultaneous assessment of key fuel parameters, because the whole spectral range

Figure 1 Examples of IR gas phase spectra of selected fuel additives.

from 4000 to 400 cm^{-1} can be used to gain molecule-specific information.

The main FTIR spectroscopic work on middle distillate fuels is focused on the direct investigation of gasoline properties, and particularly of regulated components such as benzene and oxygenates,[14,15] as well as on deriving properties like the carbon/hydrogen ratio, aromatic hydrocarbon content, cetane index, refractive index, heat of combustion, viscosity and density. Particularly, in combination with multivariate (chemometric) data evaluation procedures, even derived values of gasoline properties such as the motor and research octane number (MON, RON), total aromatic, olefinic and saturated hydrocarbon content or total oxygen content are accessible.

In general, all methods collect an FTIR spectrum of a fuel sample in order subsequently to relate the resulting spectra either to a particular fuel additive/component or to a correspondingly selected fuel property value. Most methods involve additional multivariate (chemometric) data evaluation strategies enabling full automation of data processing, as well as the possibility of detecting the smallest changes in the IR spectrum.

Two main sampling techniques can be distinguished using either ATR or micropath transmission cells, the latter frequently combined with a flow injection analysis (FIA) arrangement for sample handling.

3.2.1 Fourier Transform Infrared/Attenuated Total Reflection

ATR has become a widespread sampling technique in FTIR analysis since the introduction of internal reflection spectroscopy (IRS) by Harrick in late 1960s.[16] The evanescent field can be used to probe solid and liquid samples adjacent to the surface of a so-called ATR crystal, usually made from materials such as zinc selenide (ZnSe) or germanium (Ge). While circular ATR cells are also available, less expensive horizontal ATR configurations using conventional planar crystals with approximately 12 internal reflections are applied in the main, ensuring reproducible baselines and cross-contamination-free spectra following successive sampling.[5,17–19] The top side of the ATR crystal is usually enclosed by a gasketed cover in order to reduce the evaporation and allow fuel samples to flush through as schematically illustrated in Figure 2a.

The penetration depth (d_P) of the IR radiation depends on the wavelength of the incident light (λ), the refractive indices of the waveguide (n_1) and the surrounding medium ($n_2, n_2 < n_1$) and on the angle of incidence (θ), Equation (1)

$$d_P = \frac{\lambda}{2\pi\sqrt{n_1^2 \sin^2\theta - n_2^2}} \quad (1)$$

Typically, the penetration depth lies around 2 μm within the fingerprint region of the MIR range.

Following FTIR/ATR measurements evaluated with a partial least squares (PLS) spectral decomposition technique, Fodor et al. report reproducibility values for the

parameters listed in Table 1, including the boiling point at 50/90 vol% condensate and the end boiling point, that match or improve upon the ASTM reproducibility values of the respective standard procedures.[5] Furthermore, the measurement time of a single sample could be reduced to 1 min and the sample volume reduced to 2 mL, attesting to the potential of FTIR/ATR measurements combined with multivariate data evaluation.

3.2.2 Fourier Transform Infrared/Transmission Cell

The use of inexpensive flow cells with a very small optical pathlength, typically between 0.1 and 0.015 mm, enables to determine the concentration of various fuel components by a simple transmission measurement as schematically depicted in Figure 2b. The windows of such cells are usually made from IR-transparent materials such as potassium bromide (KBr), calcium fluoride (CaF) or zinc selenide (ZnSe) providing access to a spectral range down to 400 cm^{-1}.[20] Coupling such a measurement cell with an FIA system enables automated, simple and rapid sampling with the possibility of continuous monitoring.[21,22] Following the Lambert–Beer law, quantitative determination of fuel components is possible relating the absorbance (A) to the molar extinction coefficient (ε), the optical pathlength (l) and the concentration (c) by, Equation (2)

$$A = \varepsilon c l \tag{2}$$

Gallignani et al. report the detection limits of 0.02 vol% benzene with gasoline samples diluted 1 : 9 in hexane by

Figure 2 Combination of FTIR spectroscopy with (a) an ATR system, (b) a micropath transmission cell or (c) GC.

simply evaluating the peak height of the characteristic benzene absorption band at 675 cm^{-1}.[21] Coupling with a flow injection manifold ensures reproducible sampling and dilution conditions as demonstrated by comparison with results obtained by GC recommended as an ASTM reference method (D 3606-91). Owing to the miniaturized flow-cell the reagent consumption is kept at a minimum.

This method was later extended successfully to determine toluene (0.01–2.0 vol%) and MTBE (0.035–2.0 vol%).[22,23] Using the same procedure, López-Anreus et al. demonstrated the possibility of determining benzene, toluene, and MTBE in gasoline after vaporization at 90 °C and subsequent determination in an IR multiple pass gas cell in combination with a flow injection system.[24]

3.3 Infrared Filter-based Instrumentation

Filter-based IR instruments utilize only selected bands of the MIR spectral range containing the absorption features of interest. The main advantage compared to FTIR spectroscopy using the information content of the whole spectrum can be seen in the considerably lower costs of the spectroscopic equipment. Owing to full automatization and compactness such instruments are ideally suited to on-site determination of fuel components.

Filter spectrometers use a simple light source emitting MIR radiation, such as a black body filament, which is modulated by a chopper or can be pulsed. The IR beam is guided through a sample cell with fixed optical pathlengh, either in transmission or ATR configuration, to an appropriate IR detector, e.g. MCT (mercury cadmium telluride), DTGS (deuterated triglycine sulfate) or pyroelectric. Fixed frequency narrow bandpass filters usually mounted on a filter wheel are used to select the frequency range of interest.

All approved ASTM methods listed in section 3.6 involving MIR spectroscopy (except GC/FTIR coupling) allow the use of filter instruments as well as FTIR spectrometers.

3.4 Gas Chromatography/Fourier Transform Infrared

The application of the combination GC with FTIR for the determination of oxygenates in gasoline was mainly driven by the fact that conventional GC methods using O-FID or AED gave problems with the reliability or hydrocarbon interference.[25,26] Primary chromatographic separation enables detection and resolution of impurities, for example, from the feed ethers during the blending procedure.

Within GC/FTIR the GC column is directly interfaced to the gas flow cell of an FTIR spectrometer using the so-called light pipe technique with a heated connection as indicated in Figure 2c.

Figure 3 Schematic selective absorbance (wavelength) chromatogram from 1250–1000 cm^{-1} of 1 vol% of typical additives in gasoline. 1,2-Dimethoxyethane serves as internal standard.[11] The unlabeled peaks represent hydrocarbons. 1, methanol; 2, ethanol; 3, 2-propanol; 4, *t*-butanol; 5, 1-propanol; 6, methyl-*t*-butylether; 7, 2-butanol; 8, diisopropylether; 9, *i*-butanol; 10, ethyl-*t*-butylether; 11, 1,2-dimethoxyethane; 12, 1-butanol; 13, *t*-amyl-methylether.

Using selective absorbance reconstruction from the obtained IR spectra, results in a so-called selective absorbance (wavelength) chromatogram as an example are shown in Figure 3, with the most important components indicated as lines.[27] The reconstruction frequency for each compound is determined by the absorbance maximum in the region of interest, $\pm 4\ cm^{-1}$, using the C–O stretching region for alcohols and ethers and the aryl C–H out-of-plane bending region for aromatics, respectively.[28,29] Thus, selectivity over coeluting hydrocarbons is achievable. The separation shows sufficient resolution of all major compounds. ETBE and *i*-butyl alcohol can be separated more clearly by starting at a lower oven temperature and accepting an increased analysis time.

In conclusion, the combination of GC and FTIR yields good selectivity over hydrocarbons for C_1–C_4 alcohols and C_5/C_6 ethers using appropriate absorbance reconstruction frequencies. Diehl et al. have extended the applicable range of GC/FTIR to the quantification of BTEX (benzene, toluene, ethylbenzene, xylene) and 25 individual aromatic hydrocarbons, which presents an alternative method to the ASTM method D 3606 for benzene, in respect of the proposed ASTM approach using GC/MS for the determination of the aromatics.[30,31]

Since 1996 GC/FTIR has been approved as an ASTM standard (D 5986) as detailed in section 3.6.2.

3.5 Chemometrics

The majority of methods presented here take advantage of the exceptionally high information content of IR spectra in the range of 4000–600 cm^{-1}, without including methods combined with separation techniques. Using these, data fuel quality properties such as initial/final boiling point, density, viscosity, aromatic and oxygenates content, and so on can be predicted. In order to gain sufficient accuracy from these measurements, so-called chemometric data evaluation methods have turned out to be a valuable tool supporting data interpretation and automated evaluation of the spectra obtained.

Commonly, these methods require a set of calibration samples to train the system using their IR spectra, which are usually mean centered beforehand.[32] Subsequently, an external set of new test samples is necessary, which has to be uncorrelated with the calibration set, in order to assess the capabilities of the respective multivariate data evaluation method.[33] As a measure of the quality of the prediction provided by the model, the standard error of prediction (SEP) is generally used.[34]

The most commonly applied chemometric methods involve multiple linear regression (MLR), PLS methods or principal components regression (PCR), which are outlined below.

The best results with respect to SEP, precision, repeatability and reproducibility have been found for PLS treatment of IR spectroscopic data, which makes this data evaluation procedure most adequate for routine implementation in combination with IR techniques.[20,35–37]

3.5.1 Multiple Linear Regression

MLR determines the combination of independent prediction variables, which shows the best reproduction of the so-called dependent variables. The criterion used for selection of the best fit is generally the least squares criterion, resulting in a multiple linear correlation coefficient or the percentage of fit. The limitation of this technique can be seen in the problem of ensuring that all prediction variables are independent, because otherwise problems occur when entering the regression step.

A possible solution to this problem with respect to spectroscopic data is to apply methods, which remove a variable from and enter a variable into the set of prediction variables in a stepwise fashion, since both do not necessarily result in the same final set.

3.5.2 Principal Components Regression

PCR avoids redundant information by selecting only the primary dimension of information, the so-called variance, which is fitted by regression to the prediction variables. Irrelevant information, such as the noise in spectral data, remains in the final principal components, because only the primary principal components are usually fed stepwise into the regression model. In contrast to MLR, collinearity is avoided since principal components are respectively orthogonal. However, because the last principal components are not considered, the uncertainty remains that useful information for the prediction might be lost.

3.5.3 Partial Least Squares

PLS is probably the most interesting tool for evaluating spectroscopic data for fuel property prediction.[38,39] With this so-called canonical regression, the degree of relationship between a set of prediction variables and a set of resulting variables is determined. All the information from each source which is relevant to both sets of variables and avoids unrelated information is used, selecting the data by their predictive ability. Hence, frequent cross-validation is necessary to optimize and finally to select the PLS model with the best predictive characteristics.

Owing to achievable SEP, precision, repeatability and reproducibility, PLS treatment of IR spectroscopic data is the most useful chemometric method of automated data interpretation in order to yield standard fuel properties.

3.6 Mid-infrared Spectroscopy-based American Society for Testing and Materials Methods for Fuel Characterization

The acknowledgement of several IR-based methods for the determination of oxygenates and aromatics in fuels by ASTM attests to the fact that spectroscopic methods are gaining increasing importance in this area. The main advantages of these methods can be summarized as being cost effective, simple to run, portable and considerably faster than currently used systems.

3.6.1 Standard Test Method for the Determination of Oxygenates in Gasoline by Infrared Spectroscopy (D 5845-95)

This approved standard method[40] covers the determination of various oxygenates in gasoline (see Table 3) using either a transmission cell or an ATR configuration combined either with a filter-based MIR system, an FTIR spectrometer or a dispersive MIR apparatus.

Generally, the sample is introduced into a liquid sampling cell as shown schematically in Figure 2 and a beam of MIR radiation is imaged through the sample onto an appropriate detector. The spectral region used for data evaluation is either selected mathematically after recording a whole spectrum or in case of filter-based instruments by highly selective bandpass filters. Subsequent multivariate data analysis allows calculation of the concentration of the components of interest.

Table 3 Oxygenates determined by ASTM method D 5845

Substance	Abbreviation	Concentration range (mass%)
Methanol	MeOH	0.1–6
Ethanol	EtOH	0.1–11
t-Butanol	TBA	0.1–14
Methyl *t*-butyl ether	MTBE	0.1–20
Ethyl *t*-butyl ether	ETBE	0.1–20
t-Amyl methyl ether	TAME	0.1–20
Diisopropyl ether	DIPE	0.1–20

The driving force behind the introduction of MIR spectroscopy as standard method is the fact that it is comparably faster, simpler, less expensive and more portable than currently used methods based on GC.[2] Although this test method is not approved for testing for compliance with federal regulations, it applies well to quality control especially in the production of gasoline.

3.6.2 Standard Test Method for the Determination of Oxygenates and Aromatics in Finished Gasoline by Gas Chromatography/Fourier Transform Infrared (D 5986-96)

Using this test method[41] the quantitative determination of oxygenates and aromatics (see Table 4) in finished gasoline is enabled by combining GC with FTIR spectroscopy via a so-called light-pipe system as depicted schematically in Figure 2c.

This methods utilizes a methylsilicone wall-coated open tubular (WCOT) GC column interfaced to an FTIR spectrometer via a light pipe, enabling the compounds of interest to be detected by their characteristic absorption bands after separation in the column.

Table 4 Oxygenates and aromatics determined by ASTM method D 5986

Substance	Abbreviation	Concentration range (vol%)
Methanol	MeOH	0.1–20
Ethanol	EtOH	0.1–20
1-Propanol	1-PrOH	0.1–20
2-Propanol	2-PrOH	0.1–20
t-Butanol	*t*-BuOH	0.1–20
1-Butanol	1-BuOH	0.1–20
2-Butanol	2-BuOH	0.1–20
i-Butanol	*i*-BuOH	0.1–20
Methyl *t*-butyl ether	MTBE	0.1–20
Ethyl *t*-butyl ether	ETBE	0.1–20
t-Amyl methyl ether	TAME	0.1–20
Diisopropyl ether	DIPE	0.1–20
Benzene		0.1–2
Toluene		1–15
Total C_6–C_{12} aromatics		10–40

This method enables testing for oxygenates and aromatics simultaneously, without interference, for quality control and fuel regulation surveys. However, expensive equipment is mandatory owing to the hyphenation of two analytical techniques and the portability is limited.

3.6.3 Standard Test Method for the Determination of Benzene in Motor and Aviation Gasoline by Infrared Spectroscopy (D 4053-98)

With this method[42] the percentage of benzene in full-range gasoline can be assessed in the concentration range from 0.1–5 vol%.

Using a thin film absorption flow cell that enables transmission measurements, benzene can be determined following a correction for interference with heavier aromatic compounds and comparison with calibration blends of known benzene concentration.

3.6.4 Standard Test Method for the Determination of Benzene in Spark-ignition Engine Fuels using Mid-infrared Spectroscopy (D 6277-99)

This ASTM method[43] covers the determination of the percentage of benzene in spark-ignition engine fuels addressing a concentration range of 0.1–5 vol%. Again, a liquid sample cell is applied using either an ATR or transmission cell configuration in combination with an FTIR spectrometer or a filter-based system.

This simple method enables rapid and simple detection of benzene in fuels at low cost and can be applied for quality control in the production of spark-ignition engine fuels.

3.7 Comparison with Other Spectroscopic Techniques

Apart from FTIR spectroscopy in the MIR region, several studies describe the application of NIR spectroscopy (0.9–2.5 μm) to the determination of gasoline and middle distillate fuel properties.[44–51] Furthermore, Fourier transform Raman spectroscopic methods have been used to investigate fuel specifications.[19,52–54]

An NIR spectrum generally results from overtone vibrations and combination tones of the fundamental molecular vibrations occurring in the MIR spectral range and can be considered to be up to a factor of 1000 weaker than the associated absorption band at the fundamental frequency. In contrast to the MIR region, usually broad and overlapping absorption bands have to be evaluated applying chemometric data evaluation almost exclusively. The combination of NIR spectroscopy with optical fibers enables such analysis systems to operate remotely and on-line without sample preparation, as shown for determination of MTBE in gasolines.[55] Owing to developments in the field of MIR fiberoptic sensors it

can be expected that this extension of MIR spectroscopy will be available for gasoline analysis in the near future.

Raman spectroscopy is generally a method well-suited to hydrocarbon analysis. Owing to the strong fluorescence of gasoline samples, dispersive Raman spectroscopy using a visible light source cannot be applied. Alternatively, Fourier transform Raman using an NIR laser, usually Nd:YAG at 1.06 μm, is well suited, because the fluorescence background caused by e.g. aromatics is sufficiently reduced. Fiberoptic Raman spectroscopy has been applied to characterizing petroleum products, determining RON, MON, density and the benzene content following a PLS data evaluation approach.[56] Although appropriate for fuel analysis Fourier transform Raman spectroscopy is still not widely used because of the cost of equipment, which is not yet routinely used or established in petroleum laboratories and controlling agencies.

A special application of NIR as well as Raman spectroscopy is reported by Choquette et al., who show the application of these methods to determine oxygenates in gasoline standard reference material (SRM) as provided, e.g. by NIST (National Institute of Standards and Technology). Since these SRMs are provided in sealed glass ampules, MIR spectroscopy cannot be used since these ampules are not transparent in the MIR spectral range. Both techniques have proven to be feasible for identifying the additives MTBE, ETBE, TAME and EtOH and for quantifying the oxygen concentration to an accuracy within 0.1% oxygen mass fraction in less than 1 min.[57]

Cooper et al. conclude in a comparison of MIR, NIR and Raman spectroscopy that particularly for the detection of MTBE in gasoline, MIR spectroscopy is the method of choice because of the distinct absorption pattern and pronounced absorption bands, especially in the fingerprint region.[19]

4 THE WAY INTO THE MARKET – SELECTED EXAMPLES

Several companies have already released ready to use MIR spectroscopic systems for the determination of gasoline properties, in response to the increasing analysis demand caused by the CAA.

Portable systems applying ASTM-approved MIR technologies (D 5845) have been introduced by Grabner Instruments (IROX™), MIDAC Corporation (FOX™) and PetroSpec (GS360™ and GS1000™) and are mentioned as examples of highly integrated and compact analytical tools. While the first two instruments utilize FTIR techniques, the latter represents a filter-based system. All three instruments provide the opportunity to determine selected fuel additives as listed in Table 2 as well as derived general fuel properties as summarized in Table 1 with sufficient accuracy and according to ASTM demands.

Owing to the low sample consumption (5–7 mL), a measurement time in the range of 1 min and systems that are fully automated, commercialized MIR instruments can be considered to be a serious alternative to laboratory bound conventional fuel analysis based on separation techniques, especially if low cost per sample and portability combined with sufficient accuracy are the requirements.

5 CONCLUSIONS

Owing to the developments in the field of MIR spectroscopy and the increasing demand for fuel properties to be determined by simple, accurate and portable techniques, novel systems have been established for the direct measurement of fuel additives, taking advantage of the specificity of molecular vibrations in the MIR spectral region. Apart from sum parameters such as oxygenates, aromatic and olefinic hydrocarbon content, selected compounds such as ethers, alcohols and benzene can be measured directly using MIR spectroscopic techniques in combination with microflow cells or ATR configurations. With the possible assessment of distinct analytes, general fuel parameters such as the octane number or physical properties can be derived applying chemometric data evaluation techniques.

Considering ASTM approvals, the wide range of applications and the commercial availability of compact and rugged MIR spectroscopic instruments at a competitive price it can be assumed that MIR spectroscopy for the determination of fuel performance characteristics will be established as a routine method in a wide range of applications in the petroleum industry as well as by regulatory agencies.

ABBREVIATIONS AND ACRONYMS

AED	Atomic Emission Detection
ASTM	American Society for Testing and Materials
ATR	Attenuated Total Reflection
BTEX	Benzene, Toluene, Ethylbenzene, Xylene
CAA	Clean Air Act
DIPE	Diisopropyl Ether
DTGS	Deuterated Triglycine Sulfate
ETBE	Ethyl *tert*-Butyl Ether

FIA	Flow Injection Analysis
FID	Flame Ionization Detection
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
GC/O-FID	Gas Chromatography with Oxygen-selective Flame Ionization Detection
IP	Institute of Petroleum
IR	Infrared
IRS	Internal Reflection Spectroscopy
MCT	Mercury Cadmium Telluride
MIR	Mid-infrared
MLR	Multiple Linear Regression
MS	Mass Spectrometry
MTBE	Methyl *tert*-Butyl Ether
NIR	Near Infrared
NIST	National Institute of Standards and Technology
PCR	Principal Components Regression
PLS	Partial Least Squares
SEP	Standard Error of Prediction
SRM	Standard Reference Material
TAME	*tert*-Amyl Methyl Ether
TBA	Tertiary Butyl Alcohol
USEPA	United States Environmental Protection Agency
VOC	Volatile Organic Compound
WCOT	Wall-coated Open Tubular

fuels needed to satisfy the environmental and safety requirements of the refining and transport industries. Since the inception of the oil and automobile industries, emissions from vehicles and from fuel refineries have taken a back seat to the performance factors of the fuels themselves. In the middle of the 1900s, new environmental requirements became a commercial consideration as governments, and to a lesser extent, industrial consortia, began to impose requirements on the fuels which had little or nothing to do with performance in the engine. This article will attempt to enumerate the most prevalent of these testing specifications and provide a modest amount of information about what they involve and why they exist. At the time the original draft of this work was written in 1999, the imposition of several new regulatory criteria in the United States had just been imposed on most of the fuels production companies. Few new regulations have been enacted *in the last few years (1995+) prior to this article's printing, but there have been numerous serious proposals for such new legislation and several more geographical areas have come under existing and more stringent legislation. We have tried to assess where future regulations will lead and what specifications and tests might deal with these limits.*

In general, we will not deal here with the engine performance specifications. These are detailed far more adequately elsewhere in the literature. This article will not provide a long treatise on the formulation of transportation fuel manufacturing processes, and neither will it delve deeply into the testing methodology. Enough of these three subjects will be presented to allow the reader to put the regulatory specifications and what they entail into perspective. The emphasis is slanted towards the specification of gasoline range fuels, primarily caused by the great predominance of these commodities, but we do try to cover the heavier transport fuels in detail as well. There is considerable overlap in several of the specifications, at least in terms of methodology, even if the specification document number perhaps differs from light to heavier fuels.

The various testing specifications are presented by a fairly succinct description and are categorized by test type and by species analysis requirements. An attached glossary will enable the reader to become acquainted with the jargon of emissions compliance and refinery technology, since these are both linked to intelligent discussion of fuels production and usage.

1 INTRODUCTION

Within the United States, about 60% of every barrel of crude oil processed in a typical refinery is converted into motor gasoline and another 15% into alternative transportation fuels such as jet fuel, turbine fuel and diesel fuel.[1–3] Performance quality and contractual specification standards are many and exacting for the final product as it is carried to the retail market. These standards have been defined by more than 80 years of testing and experimentation on all kinds of combustion engines in all sorts of worldwide climatological and geographical environs.

This article is *not* about these types of standards. They are described elsewhere in the technical literature in great and accurate detail. They are mentioned here in passing only to remind ourselves that in spite of all other requirements imposed on the transportation fuel markets by regulatory agencies, the major reason for these fuels to exist is their ability to meet the specifications for modern high performance internal combustion (IC) engines. Neither is this article a detailed report about the process of making environmentally friendly fuels. Enough of this topic is presented here to allow the reader to place the types and needs of various analyses and tests within the proper context of a modern refinery but much on this subject will be missing and for a full treatise on the gasoline manufacturing process, the reader would best be served by other references.

What will be attempted here is to provide a general survey of the chemical and physical analyses of light and mid-range hydrocarbon fuels needed to satisfy the environmental and safety requirements of the refining and transport industries. Since the inception of the oil and automobile industries, emissions from cars and from fuel refineries took a back seat to the performance factors of the fuels themselves. In the mid-1960s, however, as many cities worldwide began to choke on combustion-derived air pollutants, new requirements became a part of the commercial scene as governments, and to a lesser extent, industrial consortia, began to impose requirements on the fuels which had little or nothing to do with performance in the engine.

The appropriate analytical procedures for detecting regulated chemical quantities in the laboratory and on-line in the manufacturing process will also be covered. This will not be a comprehensive manual on the analysis procedures themselves. It will not, for example, describe how to run a gas chromatograph or fluorescent indicator absorption (FIA) unit in great detail. This information, again, is well detailed in the literature and readily available to the laboratory and control instrumentation engineers and technicians who design, install, run and maintain this type of equipment. Certain exceptions will be made, to the extent of making important caveats known or of providing a specific emphasis directly related to the analytical need at hand.

The major emphasis will be on the regulatory analysis requirements for gasolines but also discussed will be jet/

turbine and diesel fuels, for completeness of coverage. As a rule, the lighter the molecular weight or gravity of the liquid, the more and easier will be the analytical choices. The heavier the fuel, the fewer simple methods are feasible.

Sections 2 through 5 will cover background and related material. It is important to consider these topics when performing analyses for control of regulatory components in fuels. The fuels must be sold so the performance characteristics must be considered, even when they are not necessarily the controlling factors in the blend as perhaps they once were. Section 6 will discuss the methodology of testing. There are numerous techniques available to the laboratory analyst and the on-line instrument designer. Most give adequate results; some give better results in one circumstance and worse in others. Where applicable such discrepancies and caveats will be mentioned. Section 7 presents the myriad of available standards and specifications that cover the realm of regulatory analysis requirements. The great emphasis will be on the American Society for Testing and Materials (ASTM) standards with several American National Standards Institute (ANSI) and International Standards Organization (ISO) standards mentioned as well. These compose 95% of the world's governing standards at this time and are usually in agreement with one another on most matters. Thus we give them emphasis, rather than unintentionally exclude any other local standards that may apply. This work is completed with a glossary of commonly used terms, that might be encountered in the fuels regulation world with emphasis on governmental acronyms, technical terms, and consortia and trade association abbreviations.

References to these three organizations and their publications of interest will not be listed as the mention of each standard is fairly obvious. The reader should note that revisions to each standard are issued on a fairly regular basis, if not each year. Thus the inclusion of specific yearly issue dates has been omitted and the reader must take care to obtain the latest version from each organization.

2 THE REGULATORY LEGACY FOR PETROLEUM FUELS

2.1 History of Fuels Formulations

Fuel driven engines of any sophistication have been available only since the mid-1880s. Several early prototypes were indirect drive – the Stanley steamer, for example – and could theoretically use any type of combustible fuel such as coal or wood. By 1890, however, the IC engine won the battle for acceptance.

At this time the most suitable fuels for the automobile were either coal tar distillates or the lighter fractions from the distillation of crude oil. During the early 20th century, oil companies were producing gasoline as a simple petroleum distillate (''white oil'') without benefit of stabilization (removal of butanes and lighter components). Automotive engines before long were rapidly being improved and required a more suitable fuel. During the 1910s, laws prohibited the storage of these unstable gasolines on residential properties, so several automotive manufacturers modified IC engines to run on kerosine. However, the kerosine-fueled engine would ''knock'' and crack the cylinder head and pistons. Research at the time demonstrated that the knock was caused by a rapid rise in pressure after ignition, not during preignition as then believed. This lead to the search for several types of antiknock agents, culminating in the common usage of tetraethyl lead for this purpose. Typical mid-1920s gasolines were 40–60 octane.[4–6]

By the 1930s, the petroleum industry had determined that the larger hydrocarbon molecules (kerosine) had major adverse effects on the octane of gasoline, and were developing consistent specifications for desired properties. In the 1940s, catalytic cracking processes were introduced,[7] and gasoline compositions became fairly consistent between brands during the various seasons.

The development of the alkyl leads (tetramethyl lead, tetraethyl lead) and the toxic halogenated scavengers (to keep the lead from plating out on valves and piston seats) meant that petroleum refiners could configure their refineries to produce hydrocarbon streams that would increase octane with small quantities of alkyl lead.[5,8] By adding increasing amounts of alkyl lead compounds, the lead response (positive octane increase) of the gasoline decreases, and so there are economic limits to how much lead should be added. The 1950s saw an increase in the cylinder compression ratios,[9] requiring even higher octane fuels. Lead levels were increased, and some new refining processes (such as hydrocracking), were specifically designed to provide hydrocarbons components with good lead response and octane.[10]

Well into the late 1960s, alkyl leads were added to gasolines for octane boost. The upper limit was $1.14\,g\,Pb\,L^{-1}$, which is well above the ''diminishing returns'' part of the lead response curve for most refinery streams. It is unlikely that much fuel was ever made at that level. Published articles on the subject usually set $1.05\,g\,Pb\,L^{-1}$ as about the economic maximum, and other literature suggests that 1970 100 research octane number (RON) premiums had about $0.7–0.8\,g\,Pb\,L^{-1}$ and 94 RON regulars $0.6–0.7\,g\,Pb\,L^{-1}$, which matches published lead response data.

Table 1 Lead response characteristics of typical refinery cut

Tetraethyl lead ($g\,L^{-1}$)	Catalytic reformate RON	Straight run naphtha RON
0	96	72
0.1	98	79
0.2	99	83
0.3	100	85
0.4	101	87
0.5	101.5	88
0.6	102	89
0.7	102.5	89.5
0.8	102.75	90

Table 1 shows the typical lead response of two basic refinery blend stocks.

Except for the lead technology and the introduction of saturated hydrocracked and alkylated stocks, only minor improvements were made for several years to basic gasoline formulations. The bulk of the automotive research effort was applied to engine design and performance optimization. Most fuel changes were implemented primarily to improve yields and octane, until the 1970s, when unleaded fuels were introduced to protect the exhaust catalysts that were also being introduced for environmental reasons. From 1970 until 1990, gasolines and corresponding refinery processes were slowly changed as lead was phased out. In 1990 the Clean Air Act (CAA) started forcing major and more rapid compositional changes in gasoline. These changes will continue into the 21st century because gasoline combustion is and still will be a major air pollution source.[11]

As the toxicity of the alkyl lead components and the halogenated scavengers became of increasing concern, alternatives were considered. The most famous of these is methylcyclopentadienyl manganese tricarbonyl (MMT), which was used in the US until banned by the United States Environmental Protection Agency (US EPA) in 1978, but is approved for use in Canada and Australia until the year 2000. It is more expensive than alkyl leads and has been reported to increase unburned hydrocarbon emissions and block exhaust catalysts. Other compounds that enhance octane have been suggested, but usually have significant problems such as toxicity, cost, increased engine wear, etc. Other such compounds include dicyclopentadienyl iron and nickel carbonyl.

Kerosine cuts have had far less change than gasolines, at least in terms of postproduction processing. Most of them are still taken from ''straight run'' streams and perhaps stabilized (redistillation) to reduce flash point for storage reasons. Though they briefly had a fling as spark engine fuels, the lighter gasoline stocks quickly took over this role. Kerosine was relegated to lamps, camp stoves, smudge pots, and to a few ''spray type'' furnaces using aerosol-forming burners. With the widespread introduction of turbine-type engines in the late 1940s, this cut became a favorite economic fuel, especially for jet engines. The product specifications for kerosine/jet/turbine fuels became more exacting but still less complex than those of gasoline.[3,8]

Diesel fuel stocks vary somewhat according to their gravity but are still produced from crude unit distillation and, since the late 1960s, from hydrocracker units. Because the compression–ignition (CI) cycle engines that they serve are far less complicated in terms of combustion initiation, less is expected of this refinery product's specification, primarily the removal of light naphtha from the front end of the distillation curve, the cloud point (for cold weather nascent wax solidification) and pour point concerns and its cetane index, diesel's analog to gasoline octane for ignition control. The relative volume usage of diesel in the commercial market is determined by heavy truck and rail needs. Advances in engine size reduction as well as in sheer numbers of these engines in the transport sector stimulated the diesel supply chain to create an expansion in mid-distillate demand. This demand was prompted by use in several diesel-fueled models of passenger cars as a response to the political disruptions in the gasoline fuel supply in the 1970s. This latter market demand factor was quickly attenuated by the 1980s environmental regulatory sector which objected to the aromatics and particulate contents of diesel engine emissions.

2.2 History of Fuels Emissions Reductions[12–17]

With the widespread post-World War II deployment of gasoline-driven automobiles, kerosine-driven jets, turbine-drive generators, and diesel-powered trucks and trains, the types and levels of fuel combustion by-products began to affect the quality of life in several areas of the developed world. Such pollutant emissions were most notable where the combustion engine was most concentrated, in large urban areas.

Cars emit several pollutants as combustion products from the tailpipe (tailpipe or exhaust emissions), and as losses due to evaporation (evaporative emissions, refueling emissions). The volatile organic carbon (VOC) emissions from these sources, along with nitrogen oxides (NO_x) emissions from the tailpipe, will react in the presence of ultraviolet (UV) light (wavelengths of less than 430 nm) to form ground-level (tropospheric) ozone, which is one of the major components of photochemical smog.

Smog has been a major pollution problem ever since coal-fired power stations were developed and domestic trash (rubbish) burns were permitted in urban areas, but these emissions were the first to be addressed and reduced

in the early 1960s. Tailpipe and crankcase emissions were responsible for the majority of ozone-forming pollutants in the late 1960s. Ozone levels in the Los Angeles basin, as a significant example, reached 450–500 ppb in the early 1970s, well above the typical background of 30–50 ppb.[18]

The first of several air pollution control acts was passed by the US Congress in 1962. While its emphasis was on industrial smokestacks and trash incinerators, the principle of government control of emissions was established and the formation of several urban and state coordinated ''smog centers'' were given legal and financial encouragement.

The CAA of 1990, now administered by the US EPA, is the primary statute governing air quality in the United States. It has been amended several times since it was first enacted in 1967. Initially, the CAA focused on vehicle-related controls, such as exhaust catalytic convertors, exhaust gas recirculation (EGR), and crankcase carbon adsorption canisters to reduce ozone-forming (NO_x and unburned hydrocarbons) and carbon monoxide emissions from automobiles.

The automotive manufacturing industry responded with major advances in emission control technology.[19] The total challenges involved were significant. The design of the engine can have very significant effects on the type and quantity of pollutants. Unburned hydrocarbons in the exhaust originate mainly from combustion chamber crevices, such as the gap between the piston and cylinder wall, where the combustion flame cannot completely use the hydrocarbons. The type and amount of unburned hydrocarbons are related to the fuel composition (volatility, olefins, aromatics, final boiling point (FBP)), as well as state of tune, engine condition, and age/condition of the engine lubricating oil.

It soon became apparent that *major* design changes to the typical automobile engine could no longer be avoided. Tuning a carbureted engine, for example, has only a marginal effect on pollutant levels. More was required, so exhaust catalysts were offered as a postengine solution that could ensure pollutants were oxidized. As engine management systems and fuel injection systems have developed and become more sophisticated, the volatility properties of the gasoline have been tuned to minimize evaporative emissions yet maintain low-exhaust emissions. Since the late 1970s, gasoline vehicle emission rates have been cut by about 80%. Overall vehicle emissions will continue to drop each year as older cars are replaced by newer ones.[20–22]

Because leaded antiknock compounds were found to destroy the performance of catalytic converters then under development, US passenger car manufacturers in 1971 began to build engines designed to operate satisfactorily on gasolines of nominal 91 RON. Some of these engines were designed to operate on unleaded fuel, while others required leaded fuel or the occasional use of leaded fuel. The 91 RON was chosen in the belief that enough unleaded gasoline at this level could be made available in the current refinery base.

Beginning with the 1975 model year, most new car models were equipped with catalytic exhaust treatment devices in addition to all the previously mentioned crankcase emissions control technology. The need for gasolines that would not adversely affect such catalytic devices has led to the large-scale availability and growing use of unleaded gasolines.

There was a further reason why alkyl lead compounds were subsequently reduced, and this was the growing recognition of the potentially toxic nature of the emissions from a leaded gasoline-fueled engine. Not only were toxic lead emissions produced, but the added lead scavengers (ethylene dibromide and ethylene dichloride) could react with hydrocarbons to produce toxic organohalogen emissions such as dioxin. Even if catalysts were removed, or lead-tolerant catalysts discovered, alkyl lead compounds would most likely remain banned because of their toxicity and toxic emissions.

2.3 History of Reformulated Fuels[11,12,15,17,20,23–25]

In spite of the emissions control advances, air quality did not improve enough in certain metropolitan areas where the impact of emissions was severe. Lead removal itself did nothing to improve air emissions control, it just kept the catalytic converters working longer. The US Congress turned to fuel formulation changes as another means of reducing emissions. As tailpipe emissions were reduced by the use of improved exhaust emission control systems, the hydrocarbons produced by evaporation of the gasoline during distribution, vehicle refueling, and from the vehicle, become more and more significant. A recent European study found that 40% of artificial VOCs came from vehicles. Many of the problem hydrocarbons are, unfortunately, aromatics and olefins that have relatively high octane values. Removing them in major quantities presented some major changes in the gasoline pool that resulted in potential engine performance problems.[26]

The CAA Amendments of 1991[13,27,28] required the US EPA to adopt regulations for reformulated gasolines (RFGs) in the USAs nine worst ozone nonattainment areas. (''Nonattainment areas'' are areas which do not meet one or more of the air quality standards established by the US EPA.) If they choose, less severe ozone nonattainment areas across the USA have the option to participate in the Federal RFG program. To date, the US EPA has received participation requests from several states, primarily in the northeast USA, and the District

of Columbia. Other less severe ozone nonattainment areas have adopted other approaches, such as limiting gasoline vapor pressure as a more cost-effective means of improving air quality. Almost every state and major metropolitan area in the United States now has its own air quality management district (AQMD).

The program requires numerous changes in fuel constituents to reduce ozone-forming hydrocarbons and toxic constituents in air. Toxic air constituents, as defined in the CAA, are benzene, butadiene, formaldehyde, acetaldehyde, and polycyclic organic matter. The US EPA has established specific limits for some of these changes. For others, the US EPA developed the emissions reduction schedule summarized in Table 2. The goals will be implemented in two phases to mitigate the effect of the necessary processing changes on the petroleum industry. Similar European Union (EU) protocols are given in Table 3.

Phase 1 (begun on January 1, 1995) is required to achieve a reduction of 15–17% of ozone-reforming hydrocarbons during the high-ozone season and an annual reduction of 15–25% of air toxic emissions from vehicles fueled with RFG. For example, with methyl tertiary butyl ether (MTBE)–RFG, benzene and butadiene emissions decrease, whereas formaldehyde and MTBE emissions increase, all within the context of a net decrease in hydrocarbons.

Phase 2, which began January 1, 2000 (except in highly noncompliant areas such as California where it has been law since 1996) is required for most of the US to achieve an annual reduction of 25–29% in ozone-forming hydrocarbon emissions, a 5–7% reduction in ozone-reforming nitrogen oxide emissions, and a 20–22% reduction in air toxic emissions. The US EPA gives refinery planners the option of meeting a ''per

Table 2 Requirements of the Federal CAA and the CARB

	Average 1990	1995 Federal CAA	CARB
Benzene (vol. %)	2	1 maximum	1.0 maximum Average: 0.8 w/1.2 cap

[a] Recent revisions to these codes have allowed for seasonality. The EN228 standard now controls RVP.
EU, European Union.

gallon'' standard or an ''averaged'' standard; in the latter case, the refiner measures the average values of their annual production against the limits. US EPA also provided two emissions level calculations (simple and complex models) to determine the levels of criteria pollutants that a particular refiner's sales block will generate.

The simple and complex models[28,29] are collections of equations and specifications which relate the emissions produced by a specific batch of gasoline, when it is used in a typical vehicle, to its composition and properties. As the names suggest, the simple model involves fewer gasoline properties than the complex model. The models are the mechanism which provides formulation flexibility to refiners, while ensuring that they meet the emission goals. The models are based on measured emissions from a variety of vehicles for a range of gasolines with different properties and/or compositions. Since different vehicles emit different amounts of pollutants, the result obtained by applying the model is an average for the total vehicle population. In 1998, most US refiners were required to use the complex model. In the three-year period 1995–1997, refiners were allowed to use either model.

As well as the US EPA requirements mentioned in this section, there are various restrictions introduced by the CAA and state bodies such as the CARB that often have more stringent limits for the above properties, as well as additional limits. The CAA specifies that some regions that exceed air quality standards had to use RFGs all year, starting January 1995. Other regions were required to use oxygenated gasolines for four winter months, beginning November 1992. The RFGs also contain oxygenates. Metropolitan regions with severe ozone air quality problems were required to use RFGs in 1995 that contain at least 2.0 wt% oxygen, reduce 1990 VOC compounds by 15%, and reduce specified toxic emissions, first by 15% (1995), then 25% (2000). Metropolitan regions that exceeded carbon monoxide limits were required to use gasolines with 2.7 wt% oxygen during winter months, starting in 1992.

Because phosphorus adversely affects exhaust catalysts, the 1990 US EPA regulations also limited phosphorus in all gasolines to 0.0013 g Pb L^{-1}, in effect making this a criteria fuels component as well.[22]

Sulfur compliance is currently (1999) around 350 ppm, well above Phase II specifications. In some regions, the average emissions are nearer 500 ppm. Large refiners will have to meet CARB-like specifications by 2004 and smaller refiners between 2006 and 2010 depending upon which piece of legislation is consulted.

California, the birthplace of RFG, is now planning to ban methyl tertiary butyl ether (MTBE)[30] as a danger to groundwater supplies. Unfortunately, no alternative ''official'' specification replaces it, and the matter currently resides in several court venues.

2.4 Regulatory Requirements for Diesel Fuels

As is the case with many environmental requirements relating to vehicular emissions, diesel fuel specifications had their origin in California and are most stringent there. There is also a likelihood that any fuel specifications begun in California may eventually spread to the remainder of the United States and might also come to Europe. It is therefore logical that any discussion regarding trends in diesel fuel specifications should start with those in California.

Particulate emissions, especially the size fraction smaller than 10 μm, are also drawing attention as a serious health concern. The current major source is from (CI = diesel) engines, while the modern spark ignition engine system has no problem meeting regulatory requirements.

2.4.1 California Specifications

The most exhaustive legislation regarding diesel fuel specifications is in place in California,[31] enacted by the California Air Resources Board (CARB). A summary of this legislation is shown in Table 4 below. The legislation affects both the sulfur content and aromatics level of diesel fuels.

The sulfur requirement for diesel fuels is 500 ppm maximum. The sulfur restriction is based on the one to one correlation of fuel sulfur content with sulfate particulate emissions. All refiners in the south coast air quality district (Los Angeles basin) have faced this sulfur requirement since 1985.

The aromatics requirement is 10% maximum for large refiners and 20% maximum for small refiners.

Table 4 CARB diesel fuel reformulation requirements effective October 1993

	1990 Average	Large refiner	Small refiner
Sulfur, wt% max	0.50[a]	0.05	0.05[b]
Aromatics, vol. % max	no spec	10	20
CN,[c] min	40	40	40

[a] The 0.50 value is the ASTM specification for #2 diesel. Most production is typically about 0.30 maximum. Since 1985, sulfur specification in the Los Angeles Basin has been 0.05 weight% max.

[b] Small refiners had until October 1994 to implement sulfur specifications.

[c] CN (cetane number) is not a legislated specification but is based on ASTM standards for #2 diesel fuel.

There has been much controversy over the aromatics requirement. The principle behind the aromatics restriction is to reduce NO_x and particulate emissions. The Coordinating Research Council (USA) (CRC), a joint industry group, has conducted a number of studies attempting to relate diesel emissions to fuel properties. Their summary report concluded that there was a significant correlation of emissions with fuel aromatics content. The correlation held for most types of emissions, including hydrocarbons, NO_x, CO, and particulates. This test program primarily utilized neat (no additive) fuels and no correlations were developed to relate emissions to CN. Subsequent studies that have included fuels with and without cetane improver have shown a much better correlation of emissions with fuel CN. Despite these arguments, the aromatics specification has remained in place. The earlier reported small degree of positive correlation of emissions versus aromatics has been sufficient to maintain the requirements.

Compounding the situation is the method specified by CARB for measuring aromatics. CARB has specified the fluorescent indicator absorption (FIA) test, ASTM D-1319, as the method for determining aromatics. This test is not applicable for many higher boiling diesel fuels. As yet there has been no change in this test specification. There have been a number of papers that have discussed various methods for determining diesel fuel aromatics.[32,33]

There is one option for a refiner to bypass this maximum aromatics requirement. CARB has defined the properties of a reference diesel fuel. This fuel must be derived from straight-run diesel stocks from crude oils that are typically run in California refineries. The reference fuel must then meet the requirements shown in Table 5. The key parts to these requirements are the 10% aromatics requirement and the relatively high natural CN of 48. In order to qualify as an alternative fuel, a specific side-by-side emissions test is performed with the reference fuel and the alternative fuel. If the alternative fuel emissions meet or better those of the reference fuel, the alternative fuel can be qualified. Certain properties of the alternative fuel then become new specifications for that refiner. These properties are also noted on Table 5. While many California refiners are pursuing this option, it still may involve a tightening of specifications. Some estimates indicate that a qualifying alternative fuel may require an aromatics content of 15–25% and a CN in the range of 48 to 52.

One major southern California refiner claims to have a new clean diesel fuel that will surpass Phase II limits, provide higher cetane, reduce NO_x emissions by 5% and reduce particulates by 15%. If true, this may become the future specifications for RFG.

2.4.2 United States Environmental Protection Agency Diesel Fuel Specifications

These specifications include the lower sulfur requirement of 0.05 weight% maximum. Rather than an aromatics specification, the US EPA has proposed a minimum cetane index of 40. This type of specification is thought to be more reasonable with respect to emissions control. Current ASTM specifications for Number 2 Diesel call for a minimum CN of 40. Thus, unless a refiner is using a lot

Table 5 CARB reference fuel specifications

	Reference fuel		Alternative fuel critical property
	Large refiner	Small refiner	
Sulfur content, ppm max	500	500	Yes, 500 ppm max
FIA aromatics, % max	10	20	Yes
Polycyclic aromatics by mass spec, wt% max	1.4	4.0	Yes
Nitrogen, ppm max	10	90	Yes
Natural CN, min	48	47	
Specific gravity (deg API)	0.830–0.860 (33–39)	0.830–0.860 (33–39)	
Viscosity at 40 °C, CST	2.0–4.1	2.0–4.1	
Distillation, D-86, C			
IBP	171–215	171–215	
10% Recovery	204–254	204–254	
50% Recovery	243–293	243–293	
90% Recovery	288–321	288–321	
EP	304–349	304–349	
CN			Yes
Additive package			Report

API, American Petroleum Institute; IBP, initial boiling point; EP, end point; CST, centistokes.

of cetane improver, the cetane index specification will not be a significant change. It could have an impact on refiners who use large quantities of fluid catalytic cracker (FCC) cycle oil in their diesel pool. Refiners with large runs of highly naphthenic crudes could also be affected. This is typically much of California's refining feedstock base.

Depending on the implementation of the California specifications, there will probably be some carry over to the remainder of the country. In the future, this might include some type of aromatics specification or a further increase in the minimum cetane index.

2.4.3 European and Worldwide Diesel Specifications

In much of western Europe, the sulfur specification is 0.30 weight% maximum. Sweden, Germany, and the Netherlands have reduced the sulfur specification to 0.20 weight%. The EU may move toward reducing the sulfur limit, although certain countries may again take the lead. Values that have been discussed range from 0.15 weight% down to the California, US, level of 0.05 weight% (500 ppm wt).

At present, there are no specific aromatics or cetane requirements for EU diesel. The large percentage of the diesel pool is from straight run stocks, so cetane tends to be inherently high. Sweden has tightened aromatics levels in what is called ''city diesel'' at 350 ppm. As more and more heavy oil conversion units are constructed, this picture may change and more universal limitations on aromatics and cetane may be expected.

The rest of the world still does not worry about diesel, with the exception of a few notable Asian countries, and Brazil, which recently has brought nearly all fuel sources under the 300 ppm limit.[34]

2.5 Future Regulatory Trends

The dramatic rush by refiners worldwide to install regulatory controls in the mid 1990s was mercifully tempered by a minimum of new edicts about what specifications had to be met. The cost of meeting even US EPA Phase I requirements was too much for many US refiners, particularly those with a capacity under 50 000 BPD (barrels per day). Dozens of them were merged, closed or downgraded to oil storage terminals, simply from the excessive cost of making regulation gasoline in a competitive market. Refiners in California had a four-year lead on the rest of the country as the CARB standards basically matched US EPA Phase II. As the year 2000 approached, another round (though smaller than the first) of capital spending began in those remaining refineries that had not yet complied with the Phase II specifications.

Based on the fact that the last major legislation was written in 1991 for this regulatory activity, it would be reasonable to assume that within the next three to four years there will be further tightening of some of the standards in Tables 2, 3, 4, and 5. There is currently a rather heated debate on sulfur levels in gasoline and total aromatic content in all fuels. One can only expect the limits on both of these to go down. It is also likely that total reductions of all regulated components will be mandated based on some 1998–2000 timeframe emissions average criteria. There will also be a push to reduce nitrogen and more of the VOCs. One can examine the proposed Tier2 regulations being proposed[35] that now extend to sports utility venicles (SUVs), minivans, and light duty trucks.

The one exception to this trend to tighter specifications may be in the amount and types of oxygenate used. There has recently been a flurry of data and instances detailing contamination of groundwater supplies by MTBE, one of the more prevalent gasoline oxygenates. There are also some credible court challenges to the effectiveness of oxygenated compounds in reducing smog-forming components in air. It may well be a better idea to reduce such emissions by lowering sulfur content drastically, although this idea is also currently based more on circumstantial evidence rather than theoretical considerations.

3 CHEMICAL COMPONENTS OF PETROLEUM-DERIVED FUELS

Gasoline is a volatile mixture of liquid hydrocarbons suitable for use in spark-ignition internal combustion (IC) engines. Gasoline is formulated from the lighter ends of refinery runs and generally contains petroleum molecules having between four and 12 carbon atoms. This material is sometimes called light naphtha in the industry. Gasoline also typically contains small amounts of additives to prevent icing and corrosion and to improve engine performance. Refiners add high-octane oxygenates such as ethanol, methanol or MTBE or aromatics such as benzene, toluene or xylene to enhance octane. Kerosine and diesel stocks have slightly heavier components than gasoline averaging about 2–4 carbon numbers heavier than gasoline respectively on a size distribution scale. This material is often referred to as heavy naphtha.

3.1 Crude Oil Chemical Mixture Components[7,20,21,36–39]

It is generally accepted that the origin of crude oil is from plant life up to 3 billion years ago, but predominantly from 100 to 600 million years ago. The molecular structure of the hydrocarbons and other compounds present in fossil fuels can be linked to the leaf waxes and other plant molecules of marine and terrestrial plants believed to exist during that era. There are various biogenic

marker chemicals such as isoprenoids from terpenes, porphyrins and aromatics from natural pigments, pristane and phytane from the hydrolysis of chlorophyll, and normal alkanes from waxes, whose size and shape cannot be explained by any known geological processes. The presence of optical activity and the carbon isotopic ratios also indicate a biological origin.

Hydrocarbons are any molecules that just contain hydrogen and carbon, both of which are fuel molecules that can be oxidized to form water (H_2O) or carbon dioxide (CO_2). If the combustion is not complete, carbon monoxide (CO) may also be formed.

The way that hydrogen and carbons bond determines which hydrocarbon family they belong to. If they only hold one common bond they are called ''saturated hydrocarbons'' because they cannot absorb additional hydrogen. If the carbons hold two common bonds they are called ''unsaturated hydrocarbons'' because they can be converted into ''saturated hydrocarbons'' by the addition of hydrogen to the double bond. Hydrogens are omitted from the following protocol for convenience, but if one remembers C has between one and four bonds maximum, H has one bond only, and O has two bonds only, the full structures of most hydrocarbons can be quickly drawn.

Gasoline contains over 500 hydrocarbons that may have between 3 and 12 carbon atoms, and gasoline used to have a boiling range from 30–220 °C at atmospheric pressure. The boiling range is narrowing as the initial boiling point (IBP) is increasing, and the FBP is decreasing–both changes are for environmental reasons. Detailed descriptions of structures can be found in any chemical or petroleum text that discusses gasolines.

Saturated hydrocarbons (paraffins, alkanes) tend to burn in air with a clean flame and form the stable, majority compositional segment of gasolines. They are subdivided into normal, iso and cyclic alkanes

- Normal alkanes have a continuous chain of carbon atoms (C_nH_{2n+2}), for example normal heptane **(1)** is

(1)

or C_7H_{16}.

- Iso alkanes have a branched chain of carbon atoms (C_nH_{2n+2}), for example isooctane **(2)** (or 2,2,4-trimethylpentane) is

(2)

or C_8H_{18}.

- Cyclic alkanes (naphthenes) have a circle of carbon atoms (C_nH_{2n}), for example cyclohexane **(3)** is

(3)

or C_6H_{12}.

Unsaturated hydrocarbons contain one or more double bonds between carbon atoms.

- Alkenes (olefins) have carbon–carbon double bonds (C_nH_{2n}), for example 2-methyl-2-butene is **(4)** or C_5H_{10}.

(4)

These components are unstable and reactive with several chemicals, including themselves (polymerization) and are the principal ''gum'' formers in fuels. They also tend to burn in air with a smoky flame and typically have a foul smell. They are very rarely found to any extent in natural ''straight run'' cuts or in hydrotreated feedstocks but are a significant component of thermally cracked stocks such as from the FCC or Coker refinery units.

- Alkynes (acetylenes) have carbon–carbon triple bonds (C_nH_{2n-2}), for example acetylene **(5)**

(5)

or C_2H_2.

These are even more unstable, but are only naturally present in trace amounts, and only to a small extent in some poorly refined gasolines.

- Arenes (aromatic compounds) have one or more ''benzene-type'' rings with highly unsaturated but highly stable intercarbon bonding. For example benzene **(6)**

(6) **(7)**

or C_6H_6 and toluene **(7)** or C_7H_8.

These are found to a small but significant extent in most petroleum stocks and are formed in most refinery cracking and reforming processes as well. Typical aromatics levels in gasolines used to be up to 40%, but are gradually being reduced to <20%. From a performance standpoint, however, the benzene, toluene and the xylenes give outstanding gasoline performance results and are difficult to replace in the gasoline supply chain. On the minus side, aromatics attack elastomers and generate smoke.

- Polynuclear aromatics (PNAs or PAHs) contain benzene rings joined together, the simplest of which is naphthalene **(8)**

(8)

or $C_{10}H_8$.

These are high boiling, and are only present in small amounts in gasoline. The multi-ringed PNAs are highly toxic, and are not present in gasoline boiling range material but will be found in diesel stocks.

Oxygenates are mostly hydrocarbons which happen to contain oxygen, for example, ethanol C–C–O–H or C_2H_5OH and MTBE (tertiary butyl methyl ether) **(9)** or $C_4H_9OCH_3$. Their structure provides a reasonable anti-knock value, thus they are good substitutes for aromatics, and they may also reduce the smog-forming tendencies of the exhaust gases. They can be produced from fossil fuels such as methanol (MeOH), MTBE, tertiary amyl methyl ether (TAME), or from biomass such as ethanol (EtOH), ethyl tertiary butyl ether (ETBE)). Most oxygenates used in gasolines are either alcohols (C_x–O–H) or ethers (C_x–O–C_y), and contain 1–6 carbon atoms. Oxygenates are added to gasolines to reduce the reactivity of emissions, but are only effective if the hydrocarbon fractions are carefully modified to utilize the octane and volatility properties of the oxygenates. If the hydrocarbon fraction is not correctly modified, oxygenates can increase undesirable smog-forming and toxic emissions.

(9)

3.2 Typical Gasoline Mixture Components[39–41]

During the 1990s, various compositional changes to gasolines for environmental and health reasons have resulted in fuels that do not follow historical rules, and the regulations mapped out for 2000–2010 also ensure that the composition will remain in a state of flux. The reformulated gasoline (RFG) specifications, especially the US EPA Jan 1998 Complex model, will introduce major reductions in the distillation range, as is now the case in California (CARB rules), as well as the various limits on composition and emissions.

It is not feasible to list all 500+ hydrocarbons in current gasolines, but those presented in Table 6 are representative of the various classes typically present in a straight run, a conventional (pre-Phase II) and a fully RFG. A traditional fuels cut composition from a normal conversion refinery would include the components given in Table 5. Newer oxygenated fuels (bottom of Table 6) reduce the aromatics and olefins, narrow the boiling range, and add oxygenates up to about 12–15% to provide the octane.

Some of the C_{10+} components will be found in most gasolines, perhaps up to C_{14}, but volatility specifications require that very little of these be residual in the gasoline distillates. Gasoline components will more typically have C_6 to C_{10} components, with an average of around 8.

There are some other properties of oxygenates that have to be considered when they are going to be used as fuels, particularly their ability to form very volatile azeotropes that cause the fuel's vapor pressure to increase, the chemical nature of the emissions, and their tendency to separate into a separate water/oxygenate phase when water is present. The RFGs address these problems more successfully than the original oxygenated gasolines otherwise known as gasohols.

Some other fuel additives are typically formulated into the gasoline by the refiner. A typical gasoline may contain:[8,11,23,42,43]

- Oil-soluble dye, initially added to leaded gasoline at about 10 ppm to prevent misuse as an industrial solvent,
- Antioxidants, typically phenylenediamines or hindered phenols, are added to prevent oxidation of unsaturated hydrocarbons,
- Metal deactivators, typically about 10 ppm of chelating agent such as *N*,*N*′-disalicylidene-1,2-propanediamine is added to inhibit copper, which can rapidly catalyze oxidation of unsaturated hydrocarbons,
- Corrosion inhibitors, about 5 ppm of oil-soluble surfactants are added to prevent corrosion caused either by water condensing from cooling water-saturated gasoline, or from condensation from air onto the walls of almost empty gasoline tanks that drop below the dew point. If gasoline travels along a pipeline, it is possible that the pipeline owner will add additional corrosion inhibitor to the fuel,

Table 6 Fuel property characteristics of common refinery chemical components

	RON	MON	bp	Specific gravity
n-Paraffins (15% typical pre-US EPA)				
n-butane	113	114	−0.5	gas
n-pentane	62	66	35	0.626
n-hexane	19	22	69	0.659
n-heptane (0:0 by definition)	0	0	98	0.684
n-octane	−18	−16	126	0.703

dicyclopentadiene[b]	229	167	170	1.071
Oxygenates				
methanol	133	105	65	0.796
ethanol	129	102	78	0.794
isopropyl alcohol	118	98	82	0.790
MTBE	116	103	55	0.745
ETBE	118	102	72	0.745
TAME	111	98	86	0.776

MON, motor octane number.
[a] Compounds are too heavy for gasoline, but would be fine for kerosine and diesel.
[b] These olefins are not present in significant amounts in gasoline, but have some of the highest blending octanes and cetane values.

- Anti-icing additives, used mainly with carbureted cars, and usually either a surfactant, alcohol or glycol,
- Anti-wear additives, which are used to control wear in the upper cylinder and piston ring area that the gasoline contacts, and are usually very light hydrocarbon oils. Phosphorus additives can also be used for engines without exhaust catalyst systems.
- Deposit-modifying additives, usually surfactants. These include:

1. Carburetor deposits – additives to prevent these were required when crankcase blow-by (PVC, polyvinyl chloride) and exhaust gas recirculation (EGR) controls were introduced. Some fuel components reacted with these gas streams to form deposits on the throat and throttle plate of carburetors.
2. Fuel injector tips operate at about 100 °C, and deposits form in the annulus during hot soak, mainly from the oxidation and polymerization of the larger unsaturated hydrocarbons. The additives that prevent and unclog these tips are usually polybutene succinimides or polyether amines.
3. Intake valve deposits (IVDs) caused major problems in the mid-1980s when some engines had reduced drivability when fully warmed, even though the amount of deposit was below previously acceptable limits. It is believed that the new fuels and engine designs were producing a more absorbent deposit that attracted some of the passing fuel vapor, causing lean hesitation. Intake valves operate about 300 °C, and, if the valve is kept wet, deposits tend not to form, thus intermittent injectors tend to promote deposits. Oil leaking through the valve guides can be either harmful or beneficial, depending on the type and quantity. Gasoline factors implicated in these deposits include unsaturates and alcohols. Additives to prevent these deposits contain a detergent and/or dispersant in a higher molecular weight solvent or light oil whose low volatility keeps the valve surface wetted.
4. Combustion chamber deposits were targeted in the 1990s, as they are responsible for significant increases in emissions. Recent detergent-dispersant additives have the ability to function in both the liquid and vapor phases to remove existing carbon and prevent deposit formation.
5. Octane enhancers are usually formulated blends of alkyl lead or manganese compounds in a solvent such as toluene, and added at the 100–1000-ppm levels. They have been replaced

by hydrocarbons with higher octanes such as aromatics and olefins. These hydrocarbons are now being replaced by a mixture of saturated hydrocarbons and oxygenates.[23,44]

3.3 Components in Heavier Fuels

Heavier petroleum fuels have similar components, only larger on average. Most of the components described above will be present to a smaller degree with significant amounts of higher boiling components, at least for those fuels derived from crude distillation. Many of the compounds with multiple aromatic or naphthenic rings have extended side chains as well. Most of the sulfur, nitrogen, and metals are concentrated in the diesel range components and are more than likely to be embedded inside an aromatic ring (RA). Thiobenzene and dithiobenzene are typical sulfur compounds. Pyridines and pyrroles are common nitrogen contaminant species. Metallic-centered porphyrins are the primary metals species for iron, nickel, and vanadium content.

Most of the same C_6-C_{10} components will be found in most heavier distillates. Kerosine will have significant amounts of up to C_{14} (average about 10) and some diesel components may have a molecular carbon number as high as 18–20, although the average molecular number here is about 11.

4 PETROLEUM-DERIVED FUELS PERFORMANCE CRITERIA

4.1 Spark-ignition Engines (Gasoline)

The critical factors in desirable performance[17,23,41,45–47] of gasoline in a spark-ignition engine[37,38,43,48,49] are volatility, antiknock quality, storage stability, component compatibility, and intake system deposit control. Gasolines are usually determined by government regulation, where properties and test methods are clearly defined. In the USA, several government and state bodies can specify gasoline properties. The US gasoline specifications and test methods are listed in several readily available publications, including the Society of Automotive Engineers (SAE) and the ASTM. These specifications, in fact, change from year to year so they are not listed with the year designation included. To do so would condemn this work to obsolescence very quickly. The latest editions, some having only minor changes in them from previous editions, can be obtained directly through ASTM or found in the nearest technical library.

ASTM D-4814 (*Specification for Automotive Spark-ignition Engine Fuel*) is the major standard for US automobile manufacturers to follow. Some of the considerations addressed therein are discussed in more detail below.

4.1.1 Volatility Considerations

Spark-ignition engines need a volatile[8,50–52] fuel for ease in starting, fast warm-up, and good drivability. In practical terms, this means a fuel that boils in the range 30–215 °C (85–420 °F). Too light a fuel leads to poor fuel economy (volatile volume loss), carburetor icing, and vapor lock in the fuel pump. Too heavy a fuel causes cold weather starting problems, poor drivability, engine deposits, and crankcase oil dilution.

Two primary standards for measuring gasoline volatility are distillation (ASTM D-86) and Reid vapor pressure (RVP) (ASTM D-4953). Distillation measures the boiling range of the hydrocarbons that make up the finished gasoline. RVP measures the pressure that the fuel exerts under conditions approximating those in an automobile carburetor. From these, a third standard vapor/liquid (V/L) ratio, can be calculated using the procedure in ASTM D-2533. The temperature where $V/L = 20$ indicates the tolerance of modern cars to vapor lock. The higher the temperature, the less chance of hot weather stalling. At low temperatures, other factors such as drivability must be considered. These factors are also controlled by ASTM D-86.

Gasoline specifications change seasonally in most areas of the world that have distinguishable seasonality. The reason for these variations is quite simple. In the cylinder only gaseous hydrocarbons burn, so if the air is cold, the fuel has to be very volatile. In summer, a volatile fuel can boil too readily and cause vapor lock, as well as producing high levels of evaporative emissions. The solution for automobile manufacturers was to adjust the volatility of the fuel according to altitude and ambient temperature. This volatility change has been automatically performed for decades by the oil companies without informing the public of the changes. It is one reason why storage of gasoline through the seasons is not a good idea.

Even as gasoline volatility is being reduced, modern engines, with their fuel injection and computerized management systems, can automatically compensate for some of the changes in ambient conditions such as altitude and air temperature, resulting in acceptable drivability using less volatile fuel.

ASTM D-4814 defines six different classes according to location and/or season. As gasoline is distilled, the temperatures at which various fractions are evaporated are calculated. Specifications define the temperatures at which various percentages of the fuel must evaporate. Distillation limits include maximum temperatures when 10% is evaporated (50–70 °C), 50% is evaporated (110–121 °C), 90% is evaporated (185–190 °C), and the

final boiling point (FBP) (225 °C). There is a minimum temperature for 50% evaporated (77 °C), and a maximum amount of residue (2%) after distillation. Vapor pressure limits for each class (54, 62, 69, 79, 93, 103 kPa) are also specified. The US EPA has issued a waiver that does not require gasoline/ethanol blends to meet the required specifications in certain areas of the United States. ASTM D-4814 also defines five classes for vapor lock protection, according to location and/or season. The limit is a maximum V/L ratio of 20 at test temperatures of 41, 47, 51, 56 and 60 °C.

Volatility also affects combustion engine emissions. The higher boiling fractions of the gasoline have significant effects on the emission levels of undesirable hydrocarbons and aldehydes, and a reduction of 40 °C in the FBP will reduce the levels of benzene, butadiene, formaldehyde and acetaldehyde by 25%, and will reduce hydrocarbon emissions by 20%.[11]

4.1.2 Antiknock Quality

Under severe service conditions, spark-ignition engines are knock limited. High temperatures, high compression ratios, lean mixtures, and advanced spark settings lead to knock, which is the explosive combustion of the last part of the fuel/air mixture ''end gas'' drawn into the cylinder. A gasoline's chemical composition determines its ability to resist knock.

The antiknock value[18,21,49] of a gasoline is measured in two standard laboratory engine tests. Both use the same type of single-cylinder variable-compression ratio engine attached to a dynamometer with the operating conditions changed only as needed. ASTM D-2699 describes the standard for determining RON and ASTM D-2700 pertaining to motor octane number (MON).

In both standard procedures, the compression ratio is adjusted to produce a measured level of knock with the test fuel, then the knock intensity with a primary reference fuel is blended to give the same, then reblended for slightly better and finally for slightly worse antiknock performance. Because the reference fuels are known blends of isooctane (octane number of 100) and *n*-heptane (octane number of 0), the octane content of the fuel that exactly matches the knock intensity of the test fuel is its octane number. Of the two procedures, the MON test is more severe, correlating with high-speed high-temperature part-throttle service in an actual vehicle. The MON for most gasolines is lower than the less severe RON, which primarily correlates to a gasoline's ability to resist run-on, after-run, or dieseling. The difference between the two ratings ($R - M$) is called the sensitivity.

Neither test exactly correlates with actual service in a car, where driving conditions vary continuously. Actual ''road'' octane number, otherwise known as antiknock index (AKI) is a better predictor of quality, and various procedures are available to measure this value, either on the road or the chassis dynamometer. Since no two cars rate gasolines exactly alike, RON cannot be used as a control test. As a compromise, the AKI has been developed. This is the arithmetic average of RON and MON, and is sometimes called simply the $(R + M)/2$ value. Where the law requires octane numbers to be posted on gasoline pumps, AKI is posted.

Gasoline specifications are written to reflect the octane number response (ONR) of the typical car population, but they also vary with location and season. Higher ambient temperatures and engine cylinder age increase ONR, while higher absolute humidity and elevation above sea level decrease it.

The most significant determinant of octane, of course, is the chemical structure of the hydrocarbons and their response to the addition of octane enhancing additives. Several other important properties of the fuel itself affect knock. Among them are:

- Front end volatility – Paraffins are the major component in gasoline, and the octane number decreases with increasing chain length or ring size, but increases with chain branching. Overall, the effect is a significant reduction in octane if front end volatility is lost, as can happen with improper or long-term storage. Fuel economy on short trips can be improved by using a more volatile fuel, at the risk of carburetor icing and increased evaporative emissions. The ASTM standards dealing with front-end volatility are D-86, D-2887, D-323, D-4953, D-5191, and D-2533.
- Final boiling point – Decreases in the FBP increase fuel octane. Aviation gasolines have much lower FBPs than automotive gasolines. Note that FBPs are being reduced because the higher boiling fractions are responsible for disproportionate quantities of pollutants and toxins. The ASTM standards dealing with back-end volatility are D-86, D-1160, and D-2887
- Preignition tendency – Both knock and preignition can induce each other.

ASTM 4814 does not set limits for AKI, but changes in engine requirements according to season and location are discussed. Fuels with an AKI of 87, 89, 91 (unleaded), and 88 (leaded) are listed as typical for the USA. Analogous considerations for cetane number (CN) in diesel stocks are governed by ASTM D-613 and ASTM D-976.

4.1.3 Storage Stability

Gasoline deterioration in storage is caused mainly to oxidative processes. Oxidation leads to the formation

of gum, a varnish-like material that can build up in combustion chambers and intake systems, interfering with efficient engine running. In extreme cases, it can even cause ring sticking and engine seizure. To guard against this problem, refiners include antioxidants and metal deactivators, which reduce the catalytic effect of certain metals in promoting oxidation.

Specifications limit the amount of gum in fresh gasoline to 5 mg per 100 mL. These results do not correlate well with actual engine deposits caused by fuel vaporization and probably should be considered as a minimum. Laboratory oxidation tests control the extent to which oxygen will attack gasoline. Compliance with these limits usually ensures that gasolines will remain usable for up to 12 months. Any gasoline known to have been in storage longer than 6 months, however, should be retested before use. Because the oxidation rate doubles for every 10 °C temperature increase, storage conditions are important.

Storage time also increases the likelihood of a water–oxygenate phase separating from the hydrocarbon, so care should be taken with the ''shelf life'' of oxygen-containing fuels. Water tolerance via ASTM D-4814 sets the highest temperature that causes phase separation of oxygenated fuels. The limits vary according to location and month. For Alaska, north of latitude 62, it changes from −41 °C in Dec/Jan to 9 °C in July, but remains 10 °C all year in Hawaii.

Gums are usually the result of copper-catalyzed reactions of the unsaturated hydrocarbons, so antioxidants and metal deactivators are added. Existent gum is used to measure the gum in the fuel at the time tested, whereas the oxidation stability measures the time it takes for the gasoline to break down at 100 °C with 100 psi (690 kPa) of oxygen. A 240-min test period has been found to be sufficient for most storage and distribution systems.

Minimum oxidation stability tests ensure the fuel remains chemically stable, and does not form additional gums during periods in distribution systems, which can be up to 3–6 months. The sample is heated with oxygen inside a pressure vessel, and the delay until significant oxygen uptake is measured.

The ASTM standards dealing with storage stability in gasolines are D-381 and D-525.

4.1.4 Component Materials Compatibility[45,49]

Minor amounts of nonhydrocarbon material found in, or added to, gasolines can have adverse effects on engine life and performance. Phosphorus and lead deactivate oxidation catalysts, and oxygenated materials such as alcohols and ethers can cause seal and fuel-line swelling as well as promoting engine rust.

Sulfur in the fuel creates corrosion and when combusted will form corrosive gases that attack the engine, exhaust and environment. Sulfur also can poison exhaust catalysts. The copper strip corrosion test and the sulfur specification are used to ensure fuel quality. The copper strip test measures active sulfur, whereas the sulfur content reports the total sulfur present.

ASTM D-4814 specifies lead content at the following levels for:

- Leaded brands (where allowed) = 1.1 g Pb L^{-1} maximum,
- Unleaded brands = 0.013 g Pb L^{-1} maximum.

Most local jurisdictions allow for almost no lead, and trace analysis procedures may be needed to determine trace levels.

ASTM D-4814 only mentions copper strip corrosion as the ability to tarnish clean copper, indicating the presence of any corrosive sulfur compounds. Interpretation is left up to the refiner.

Maximum sulfur content via D4814 is specified at the following levels for:

- Leaded brands (where allowed) = 0.15% mass (1500 ppm) maximum
- Unleaded brands = 0.10% mass (1000 ppm) maximum

Sulfur adversely affects exhaust catalysts and is typically emitted as polluting sulfur oxides. Typical US gasoline levels are 0.03% (30 ppm) by mass.

The ASTM standard dealing with materials compatibility for gasolines is D-130.

4.1.5 Intake System Deposit Control

The intake system includes either a carburetor, throttle body injector or port fuel injector, and intake valve stem, tulip, head, and intake manifold runners. Many gasolines contain unstable components that can lead to deposit formation in these high-temperature areas of the induction system. Gasolines for use as fuels in spark-ignition engines must be able to reduce or eliminate deposit formation in critical fuel-delivery system components. Since January 1 1995, the US EPA has mandated the use of detergent additives in gasoline in order to help reduce emissions and improve air quality.

During the 1980s significant problems with deposits accumulating on intake valve surfaces occurred as new fuel injections systems were introduced.[21] These intake valve deposits (IVDs) were different from the injector deposits, in part because the valve can reach 300 °C. Engine design changes that prevent deposits usually ensure that the valve is flushed with liquid gasoline, and provide adequate valve rotation. Gasoline factors that cause deposits are the presence of alcohols or olefins.

Figure 1 Fuel performance and property relationship for gasoline.

Gasoline manufacturers now routinely use additives that prevent IVD and also maintain the cleanliness of injectors. These usually include a surfactant and light oil to maintain the wetting of important surfaces.

Figure 1 illustrates the fuel property/performance relationships of a modern gasoline.

4.1.6 Brands Differences/Additive Packages

The above specifications and standards are intended to ensure minimal quality standards are maintained, however as well as the fuel hydrocarbons, the manufacturers add their own special ingredients to provide additional benefits. A quality gasoline additive package would include:

- octane-enhancing additives (improve octane ratings)
- antioxidants (inhibit gum formation, improve stability)
- metal deactivators (inhibit gum formation, improve stability)
- deposit modifiers (reduce deposits, spark-plug fouling and preignition)
- surfactants (prevent icing, improve vaporization, inhibit deposits, reduce NO_x emissions)
- freezing point depressants (prevent icing)
- corrosion inhibitors (prevent gasoline corroding storage tanks)
- dyes (product color for safety or regulatory purposes).

4.2 Aviation Gasoline

A special grade of gasoline is aviation gasoline, called avgas for short. It should not be confused with jet fuel which is essentially a kerosine-derived turbine fuel. Avgas is for smaller spark ignition aircraft engines. Most specifications for avgas cater to the safety factors at the expense of the economics. Distillations and volatility are more tightly controlled, as are contaminant levels. The octane requirements are higher to account for both the higher engine cylinder compression ratios and the devastation that could be caused by premature valve and lifter wear if cheap gasolines were routinely available to unsophisticated aircraft owners. Most other specifications follow those of automobile gasoline, including recent US EPA/CARB regulatory requirements. Significant exceptions are mentioned below.

4.2.1 Aviation Gasoline Antiknock Numbers

Aviation gasolines were all highly leaded and graded using two numbers, with common grades being 80/87, 100/130, and 115/145. The first number is the aviation rating (lean mixture rating), and the second number is the supercharge rating (rich mixture rating). In the 1970s a 100 LL grade (low lead = 0.53-mL TEL L^{-1} instead of 1.06-mL TEL L^{-1}, TEL = tetra ethyl lead) was introduced to replace the 80/87 and 100/130. Soon after the introduction, there was a spate of plug fouling, and high cylinder head temperatures resulting in cracked cylinder heads. The old 80/87 grade was reintroduced on a limited scale.

The aviation rating is determined using the automotive motor octane test procedure, and then corrected to an aviation number (AN) using a table in the method – it is usually only 1 – 2 octane units different from the motor value up to 100, but varies significantly above that, e.g. 110 MON = 128 AN.

The second avgas number is the rich mixture method performance number (PN – they are not commonly called octane numbers when they are above 100), and is determined on a supercharged version of the constant fuel ratio (CFR) engine, which has a fixed compression ratio. The method determines the dependence of the highest permissible power (in terms of indicated mean effective pressure) on mixture strength and boost for a specific light knocking setting. The PN indicates the maximum knock-free power obtainable from a fuel compared to isooctane = 100. Thus, a PN = 150 indicates that an engine designed to utilize the fuel can obtain 150% of the knock-limited power of isooctane at the same mixture ratio. This is an arbitrary scale based on isooctane + varying amounts of TEL, derived from a survey of engines performed decades ago. Aviation gasoline PNs are rated using variations of mixture strength to obtain the maximum knock-limited power in a supercharged engine. This can be extended to provide mixture response curves which define the maximum boost (rich, about 11 : 1 stoichiometry) and minimum boost (weak, about 16 : 1 stoichiometry) before knock.[45]

The 115/145 grade has been phased out in North America (though not everywhere else in the world), but the 100 LL is still in use and has more octane than any automotive gasoline. These specifications change much more slowly than automobile fuel specifications because the market is much smaller and safety for use in older aircraft is still considered an important criteria.

The basic ASTM standard dealing with avgas performance is D-910.

4.3 Compression–Ignition Engine (Diesel) Fuels

Compression–ignition (CI) engines run on mid-distillate fuels with boiling ranges higher than that of gasoline. The best diesel fuels are ''straight-run'' stocks, derived from simple distillation of crude oil, but many commercial fuels contain a proportion of catalytically cracked material.

The important properties of diesel fuels are volatility, heating value, ignition quality, CN, viscosity, low-temperature flow, storage stability, component compatibility, and sulfur content. There is no overall defining specification for diesel fuel due to the wide variety of engine types and requirements that the fuel must meet. There are standards, however, for individual diesel fuel qualities, both economic and regulatory.

4.3.1 Volatility

The volatility of a diesel fuel has little influence on its engine performance, except as it affects ignition tendencies. The distillation range of a diesel fuel does not allow much flexibility in this regard because of the interrelationship and interdependence with other specification factors. The controlling factor is the ASTM D-86 distillation 90% evaporated temperature.

Because diesel fuels are classified as nonflammable for freight purposes, minimum flashpoint restrictions are imposed. The ASTM standards dealing with diesel flashpoint are D-93 and D-95.

4.3.2 Heating Value

Fleet operators, rail and shipping companies are concerned about fuel economy. They aim to use the fuel with the greatest heating value, provided that other specification requirements are met. The factors that influence heating value are density and mid-boiling point (bp).

4.3.3 Ignition Quality

This factor influences ease of starting, duration of white smoking after start-up, drivability before warm-up, and intensity of diesel knock at idle. Studies have correlated ignition quality with all regulated emissions. As ignition delay is reduced, the combustion process starts earlier and emissions (primarily CO and hydrocarbons) are reduced.

4.3.4 Cetane Number

Ignition delay is measured by the CN test (ASTM D-613), which uses a single-cylinder, variable compression ratio engine analogous to the octane number engine. The factor measured is ignition delay (rather than knock) at a fixed compression ratio, and it is compared with that of standard reference fuels consisting of blends of *n*-cetane and heptamethylnonane. The cetane content of the blend that matches the ignition delay of the test fuel is the test fuel's CN. It is diesel's analog to gasoline octane.

Few laboratories are equipped with cetane engines, so a number of correlations between CN and physical properties have been developed as substitute methods. Best known is the ASTM D-976 calculated cetane index, which uses the density and mid-bp of the fuel.

Diesel engines vary more widely in their cetane requirements than do automobiles in their octane requirements. In general, the slower an engine's operating speed, the lower the CN of the fuel it can use. Large marine engines can tolerate fuels with CNs as low as 20, while some manufacturers of high-speed passenger car diesel engines specify 55 CN fuel. Railroads purchase fuel to a 37 or 38 CN minimum specification, but most truck manufacturers call for a 40 or 45 minimum. CN can be increased by using cetane improvers. These additives, usually organic nitrates, boost CN by 2 to 7 numbers, depending on the dosage and type of base stock used. These additives directly contribute to NO_x emissions, however, and have come under scrutiny from various regulatory agencies.

4.3.5 Viscosity

Viscosity influences the spray pattern when the fuel is injected into the cylinder. Low-speed marine engines can use higher viscosity fuels than high-speed road transport engines, and still run without excessive smoking. Minimum viscosity limits are imposed to prevent the fuel from causing wear in the fuel injection pump.

4.3.6 Low-temperature Flow

Unlike gasolines, which have freezing points well below even the most severe winter ambient temperatures, diesel fuels have pour points and cloud points well within the range of temperatures at which they might be used. This presents no problem on ships or even in railroad applications where heated storage can be arranged. However, for on- and off-highway use, precautions must be taken to tailor the low-temperature properties of the fuel to the weather.

Seasonal blending to control cloud point (the temperature at which wax separates from the fuel) is the refiner's assurance against field problems. ASTM D-97 is the procedure used to determine a fuel's cloud and pour points. In the winter, there is an increasing tendency to use flow

improvers, polymeric additives that modify the wax structure as it builds up during cooling. These additives keep wax crystals small, so they can pass through the fine pores of fuel filters en route to the injector pump. With suitable base stocks, flow improvers can keep an engine running at temperatures as much as 10 °C below the fuel's cloud point.

In addition, pour point depressants are sometimes used in diesel fuel to ensure that it can be dispensed at low temperatures. Tests such as the cold filter plugging point (CFPP), IP 309, are used to assess the potential of a diesel fuel to have cold weather field problems.

Other ASTM standards dealing with cold environment performance, are D-2500 and D-4539.

4.3.7 Storage Stability

In storage, diesel fuels are attacked by atmospheric oxygen, which can cause deposition of varnish, and for marine fuels containing residual components, asphaltic material. Antioxidants and dispersants are added to prevent such problems, while copper metal deactivators reduce the catalytic effects of screens and other parts. In the presence of water, bacterial action can cause a build-up of slime in the storage system, leading to filter plugging. Biocides are added to inhibit bacterial growth. In cold weather areas, there is the risk of static electric charges building up during high-rate dispensing of distillate fuels. Refiners include antistatic additives in diesel blends to prevent explosions.

The ASTM standards dealing with storage stability in diesel cuts are D-381 and D-5304.

4.3.8 Component Materials Compatibility

Diesel fuels are injected into the engine through precision pumps and fine injector nozzles. Dirt and water contamination must be avoided to protect these critical components. Specifications include tight limits on water and sediment, but some fuel marketers also install final filters at the nozzles of service station pumps to protect against dirt picked up in the distribution system.

Depending on the crude source, diesel fuels contain various amounts of sulfur compounds, which yield corrosive sulfur oxides on combustion. These can cause high rates of engine wear and rapid depletion of engine oil additives. Engine manufacturers often relate oil change intervals to the fuel sulfur content.

Deposit buildup in engines is influenced by fuel quality. Fuels that leave a heavy carbon residue and contain excessive amounts of high-bp materials are prone to cause engine deposits. Therefore, limits are placed on carbon residue and ASTM D-86 90% evaporated temperature.

Again, as for gasoline, the ASTM standard dealing with materials compatibility is D-130.

4.3.9 Sulfur Content

Sulfur content is the first diesel fuel property to be widely controlled by legislation aimed at limiting exhaust emissions. Sulfur is present in all crude oils and refined products. During combustion, sulfur compounds burn to form acidic by-products, SO_2 and SO_3, which form sulfates in the exhaust gas stream. Sulfates are part of a diesel engine's particulate emissions; therefore, controlling fuel sulfur level reduces the level of sulfate pollutants.

4.3.10 Water Content

All diesel fuels contain small amounts of water. The amount that a fuel can hold is controlled by hydrocarbon type and distribution, and bulk temperature. As temperature decreases, the amount of water dissolved in the fuel will also decrease and may lead to a water layer forming on the bottom of the storage vessel. This layer should be minimized by draining the tank regularly to prevent bacterial contamination and the pumping of water into the fuel distribution system. Excessive water in a fuel system can cause corrosion, filter plugging and icing (in the winter).

A tabular summary of diesel fuel performance/property relationships is presented in Table 7.

Table 7 Fuel performance and property relationships for diesel fuel

Distillation	
10%	Starting, warm-up, odor, smoke
50%	Particulates
90%	Heat content, metering
Gravity	
CN; cetane index	Cold starting, warm-up, white smoke, black smoke
Pumpability	
Viscosity	Fuel atomization, penetration, leak back, lubrication
Cold flow	Cold weather operability
Cleanliness	
Appearance	Contamination
Water and sediment	Contamination
Sediment stability	Filter plugging
Demulsibility	Engine damage
Safety	
Flash point	Safety
Miscellaneous	
Sulfur	Engine corrosion, deposits, emissions
Mercaptan	Odor, copper mercaptide gel
Carbon residue	Indicator of contamination
Ash	Engine wear, contamination
Corrosion	Corrosion of copper and brass
Acid number	Indicator of contamination

4.4 Aviation Turbine/Jet/Marine Fuels

The important properties of kerosine-derived turbine fuels are volatility, heating value, low-temperature cloud point, storage stability, component compatibility, and sulfur content. There is no overall defining specification for a generic turbine fuel because of the wide variety of engine types and requirements that the fuel must meet. There are standards, however, for individual turbine fuel types mostly defined by the type and service of the turbine involved. The most important standards are set by military requirements since jet fuels are the biggest users of this fuel stock. In spite of this, there are far fewer performance requirements than for spark or compression ignition engines. The current ASTM standard for turbine fuels performance is D-1655.

There are also some ISO standards for performance and scores of military specifications (nearly one for each country with an airforce), some of them conflicting in minor areas with the other specifications. It would seem that, unlike normal gasoline purchase customers, the military block in the world both sets the refining specifications and buys the product that they have specified and subsequently use. Quantity purchases allow for this customer perquisite. Fortunately, most of these specifications agree in important areas. If they did not, there would be major problems with some jet fuels, of which the only indication might be a crashed plane. Thus, jet fuel misspecification problems are somewhat self-limiting.

The overall performance standard for this fuel is D-1655.

4.4.1 Volatility

The volatility of a turbine fuel has little influence on its engine performance, except as it affects exhaust smoking tendencies and fuel efficiency. The distillation range of jet fuels is tightly defined by military jet engine specifications and have been so for years. As with gasoline, a controlling factor is the ASTM D-86 distillation 90% evaporated temperature.

Because turbine fuels are often handled in large quantities by numerous commercial and military installations, minimum flash point restrictions are imposed. ASTM D-56 is the applicable standard here. This also makes it easier for refiners to store jet cuts than for them to store the more volatile gasoline blend stocks and products.

A consideration for static electricity buildup (non-ionic, nonelectrolyte fluid flowing through a metal conducting pipe tends to do this for gasoline, kerosine, and diesel cuts) should be mentioned. There is no such standard for gasoline or avgas, although the problem can exist with them as well. The diesel flash point and flammability characteristics generally (not always, but typically so) rule out severe static susceptibility. The typical military quartermaster loves to have specifications for nearly everything; therefore the static ignition on jet fuels is maintained. ASTM D-4856 is a rough composite of several historical military specifications combined with some practical materials engineering and grounding practices.

4.4.2 Heating Value

The same considerations apply here as for the diesel fuel heating value commentary.

4.4.3 Low-temperature Flow

Unlike gasolines, which have freezing points well below even the most severe winter ambient temperatures, kerosines would normally have cloud points well within the range of temperatures at which they might be used. This presents no problem on ships or even in railroad applications where heated storage can be arranged. Wax formation in high-altitude aircraft is extremely hazardous to flow of the fuel to the aircraft engine. Since ambient temperatures in such an environment may be $-20\,^{\circ}\mathrm{F}$ ($-29\,^{\circ}\mathrm{C}$) or less, jet fuels have a large number of guidelines for what they may contain. Error in specification formulation for jet fuels is always on the side of safety.

4.4.4 Storage Stability

In storage, jet/turbine fuels like gasoline are also attacked by atmospheric oxygen, which can cause deposition of varnish and gums, but since these fuels typically are used in high volumes, long-term storage problems are not of as much concern. Usually military specifications prescribe refining procedures that minimize the amount of oxygen-sensitive contaminants in the fuel as delivered. Water is always a problem, however, especially in humid climates. In the presence of water, bacterial action can cause a buildup of slime in the storage system, leading to filter plugging. Biocides are added to inhibit bacterial growth. In cold weather areas, there is the risk of static electric charges building up during high-rate dispensing of distillate fuels. Refiners include antistatic additives in jet fuel blends to prevent explosions.

4.4.5 Component Materials Compatibility

Kerosine fuels are injected into the engine through pumps and injector nozzles. Dirt and water contamination must be avoided to protect these components, but the greater need is to protect the turbine engines and their high-speed moving parts. Most jet specifications include tight limits on water and sediment, but some fuel marketers also install final filters at the nozzles of aircraft service

Table 8 Fuel performance and property relationships for jet fuel

Performance characteristic	Fuel property
Engine fuel system deposits and coke	Thermal stability
Combustion properties	Luminometer number; smoke point; aromatics; percent naphthalenes
Fuel metering and range	Gravity; heat of combustion
Fuel atomization	Distillation; viscosity
Compatibility with elastomers and metals in fuel system	Mercaptan sulfur; sulfur
Fuel cleanliness, handling, and storage stability	Flash point; existent gum; potential gum

truck distribution pumps to protect against dirt picked up in the distribution system. Other contaminants are generally specified as they are for gasoline and are tested for in exactly the same fashion.

A tabular summary of turbine fuel performance/property relationships is presented in Table 8.

4.4.6 Benzene and Toluene

The governing performance standard here is ASTM D-3601.

5 SOURCES AND FORMULATION OF TRANSPORT FUELS

5.1 Refinery Configuration[1,3,7,12,32,53]

5.1.1 Introduction

Because the greatest abundance of transportation fuels in the world is derived from petroleum-based hydrocarbons, it makes sense to examine the workings of a petroleum refinery briefly. As mentioned before, naturally occurring petroleum has in its mix light naphtha, heavy naphtha, and light gas oil used respectively in gasoline(automobile and aviation), kerosine, jet/turbine fuels and diesel products. In the earliest days of the industry, these products were simply distilled from the feed oil. It has been said that the modern IC engine was basically built as a means to take advantage of the cheap and abundant ''white gas'' by-products of the refining of petroleum into lamp oil, lube stock and wax products more in demand at the end of the 19th century. Now, of course, the automobile and its demands virtually determine the market for petroleum and its products worldwide.

Today's sophisticated transport machinery has more exacting specifications than can be typically met by using direct distilled, or as commonly known, ''straight-run'' fractions. In order to meet these requirements, refineries are designed to make a number of motor fuel components and streams which vary greatly in octane, volatility and other drivability parameters.

Refineries not only differ in size (BPD of crude processed), they comprise different processes and operations (configurations). The configuration of a refinery depends primarily upon the type of crude(s) available as feedstock and upon the product slate requirement. In general, the products which dictate refinery design are relatively few in number, and the basic refinery processes are based on the high-volume products such as gasoline, jet fuel and diesel fuel. Storage and waste disposal are expensive. It is necessary to sell or use all of the items produced from crude oil even if some, like heavy fuel oil, must be sold at a price less than the crude oil cost. Careful economic balances are required to determine whether certain crude fractions should be sold as is (straight-run) or further processed to increase their value.

5.1.2 Types of Refineries[35]

The simplest and earliest configuration is the skimming (topping) refinery, a schematic of which is shown in Figure 2. Here the major processing step is crude oil distillation, the object being to remove the lighter fractions from the residuum. When only one distillation column is used, it is operated at atmospheric pressure. Typical products will be gases, light naphtha, heavy naphtha, light gas oil, heavy gas oil and a 675 °F+ residuum. A second distillation column operating under vacuum may be added to gain more, and heavier, gas oil. This in turn produces less, but a heavier (975 °F+), residuum.

The liquid sidestream products are further stabilized in individual strippers before leaving as ''straight run'' naphtha, and so on. Contaminants are not removed in straight-run products and are present in proportion to their distribution in the whole crude. Also the quality

Figure 2 Topping plant scheme.

Figure 3 Modern conversion refinery.

(octane, pour point, contaminant levels, etc.) of these straight-run oils is usually at a minimum level.

A more complex configuration results when hydrotreating[54] processes are added to remove contaminants from the straight-run oils (hydroskimming refinery). Figure 3 shows a simplified process block flow diagram of this kind of plant. Olefins and aromatics are also saturated in hydrotreating. To supply the hydrogen consumed in these processes a catalytic reforming operation is often included which itself greatly increases the octane pool potential of the refinery (at the expense of adding a lot of benzene and aromatics to the mix). If reforming does not produce sufficient hydrogen, a hydrogen manufacturing unit must be added, too.

Hydrotreating increases the quality of the liquid products primarily from an environmental cleanliness standpoint by removing the sulfur, nitrogen, and some metals impurities. In some instances, benzenes and other aromatics can also be removed by hydrotreating, though this option is fairly expensive.

Catalytic reforming increases the quality of the naphtha by raising the octane number rating of the clear unleaded gasoline fraction.

When the market for gas oil products is smaller than their yield, they are cracked to lower boiling range sales products such as liquefied petroleum gas (LPG), gasoline and diesel fuel. This is done by catalytic cracking (FCC unit) or hydrocracking units. Because the product slates of these two processes are different, market requirements must be considered in choosing which one to use. In most large refineries, both types of cracking will be used.

Hydrocracking consumes a large quantity of hydrogen (1500 to 2500 standard cubic feet per barrel) which is much greater than that produced by catalytic reforming. A hydrogen manufacturing plant is included in these refineries to supply this excess. The need for a separate hydrogen plant as well as the high operating-pressure requirements, make hydrocracking an expensive operation. This is made up for by the significantly higher quality products which are formed.

If the residuum (heavy fuel oil) produced exceeds the market demands, some type of residuum treatment process must be incorporated. In a conversion refinery a visbreaker or delayed coking or fluid coking is used to crack the residuum to naphtha, distillate and gas oil product. When the coke market is small and the

refinery can use low British Thermal Unit (Btu) fuel gas, flexicoking might be used. Alternatively, a residuum hydrocracker may be used to upgrade the entire stream.

The liquid products from a coking process generally are not very stable. They contain olefins and active aromatics and have high sulfur and nitrogen contents. These liquids are usually hydrotreated to improve their quality.

Figure 3 is a simple block flow diagram of a modern conversion refinery. A comparison of Figures 2 and 3 graphically illustrates some of the increased complexity of modern refinery processing. This particular example has three processes for handling the vacuum residuum: solvent deasphalting, delayed coking and fluid/flexicoking. Many refineries, particularly in cold climates, do find it economical to produce a significant amount of heavy fuel oil in addition to fuel-destined naphtha and coke by-products.

Another option for residuum processing, if the main crude has the proper makeup, is lubricants production. Not all crudes have an abundance of good lube stock components. The main feedstock for lube oil products is usually heavy vacuum gas oil. Lube oil can also be made from hydrotreating/hydrocracking products so there can be a variety of configurations to include this capability. In the refinery of Figure 3 several additional steps would be added. The lube oil feedstock (vacuum gas oil, deasphalted oil, etc.) would be sent to a solvent extraction unit. Here aromatics and other undesirable components are removed to produce a stable oxidation-resistant lube oil product. The lube oil is further treated by solvent dewaxing to lower the pour point. The dewaxed oil is then clay treated to decolorize it to produce the final product.

When a refinery has thermal cracking (visbreaking or coking) or catalytic cracking, significant quantities of light olefins (ethylene, propylene, butadiene, etc.) are produced. Some refineries include processes such as ethylene/propylene separation and butadiene separation in addition to aromatics (benzene, toluene, xylenes) separation. These materials are then sold as petrochemical feedstocks.

A critical process for making reformulated fuels is the alkylation unit. This unit takes isoparaffins and combines them with olefins to produce longer-chain branched naphtha molecules. By using only C_3 to C_5 olefins with isobutane, high octane, low olefin, low RVP, no-aromatics gasoline can be made. While the alkylate product is an extremely valuable commodity, the capital and operating costs of alkylation units are quite high and are catalyzed by either sulfuric or hydrofluoric acid which present refiners with some safety and environmental concerns of their own.

Table 9 shows a textual explanation of the source and distributions of typical refinery streams.

5.2 Fuels Blending

Modern gasolines have such a variety of specifications to be met in each blend[15,18,55–59] run, as many as 30 including those for both performance and environmental criteria. Few if any of the process unit naphtha streams in the refinery (a dozen at most) could singly meet them all. This represents a mathematical imbalance that can be rectified only by using a fairly sophisticated blend procedure to minimize both deviations from specification and economic giveaway. Some of the streams are more expensive to make than others and if one particular blend were to take too much of a more desirable feedstock, say alkylate (low RVP, high octane, no aromatics or olefins), the refinery would be left with no choice but to use the other stocks for its subsequent product demand. This, in turn, gives a greater risk of making off-specification material or will force the refinery to cut production capacity in other units in order to restore blend stock ratios. Neither option should be used very often in today's competitive market. A downgrade of premium fuel to regular grade, or from CARB spec to US EPA Phase I specification may cost as much as $4.00 per barrel of product which is a $280 000 loss for a 70 000 BBL blend run.

The specifications themselves may also vary in type and approach to blending implementation. The normal drivability and regulatory specifications mentioned elsewhere in this article are diverse indeed. Most are expressed as either minima or maxima, some being one or the other, others with widely varying bounds on both sides of a tolerance range. A few such specifications, octane rating being the most prominent, may have tolerance limits so narrow as to be essentially a fixed value. In this case the minimum specification would be determined by commercial or contractual needs and the maximum might be from the standpoint of refinery ''giveaway'' economics.

Figure 4 shows a basic analyzer-control schematic for fuels blending.

Commercial methods for blending motor fuels may be one of two kinds, batch tank blending or the more modern in-line blending. Small sequential batch-to-receiving tank blending (the traditional way) is normally time-consuming and involves trial-and-error testing until a given batch meets specification, making allowances for testing errors. Modern refineries have generally adopted some modification of direct in-line blending or massive blend tank (50 000 BBL + at a time) batching with multiple simultaneous stock feeds. These methods have some outstanding advantages. They are continuous (or mostly so with giant size batches) rather than batch mode, thus saving time. They provide a much closer control in meeting critical specifications and require less tankage. The multiple feedstock protocol generally prescribes

Table 9 Refinery processing source and distribution of streams

Unit	Feeds	From	Products	To
Atmospheric crude	Crude	Tankage	Gas, naphtha	Saturate gas
			Kerosine, distillate	Treating, hydrotreating, product
			Light gas oil, heavy gas oil	Hydrotreating, hydrocracking, product
			Atmospheric residuum	Vacuum, delayed coking, hydrotreating, product
Saturate gas	Gas, naphtha	Crude, hydrotreating, hydrocracking, reforming	Gas	Product
			Propane	Product

			Vacuum residuum	Coker, de-asphalting, visbreaking, product

that the blend header specification must quickly become ''on-spec'' within a certain percentage of the blend having traveled down to the receiving tank and the total blend run, plus the residual ''heel'' in the blend tank must blend together and still meet specifications. True ''in-line'' blending directly to customer carrier (pipeline, railcar, tanker) is even more stringent procedurally. The product must be ''on-spec'' almost immediately and the total blend must meet specs – there obviously is no room at all for reblends in this case.

In-line blending became a practical reality with the advent of sophisticated, automated equipment and instruments, along with distributed (computer) control systems. With this method, the first step is to produce in segregated tankage the required amounts of several appropriate blend components which, according to the blender's calculations, will result in meeting the target blend specifications when the components are blended in the proper proportions. Close control of certain specifications of these components as they are produced, particularly RVP and octane number, is achieved by continuous monitoring, using suitable automated equipment. The final step is to pump these components at controlled rates into a common line that discharges into a vessel which may be a tank, pipeline, barge, or a tanker. This operation can be activated and controlled by a suitable advanced computer control system.

Figure 5 displays the approach to final blend value of RVP and RON for an 87.5 RON regular grade of unleaded fuel. Notice the approach to the target of RVP as opposed to that of the octane. Before RFG, the giveaway strategy would have been reversed.

Figure 4 Simple in-line blender process with analyzer control.

Figure 5 An example of octane and RVP control.

5.3 Advanced Control and Monitoring of Gasoline Blending

5.3.1 Introduction[59]

The following description is a typical procedure that might be followed in the course of setting up and running a gasoline blend in a semi-batch fashion in typical runs of 20 000 to 150 000 barrels sizes depending upon the size and complexity of the refinery.

The key to success is getting all the right information to flow around the system. Blend recipes from the refinery planning group must be received in proper and timely fashion by the blend operators, who must then set up the actual plant flow paths to accomplish the blend. Historically, this function was a simple matter of verifying the availability of stocks and setting the blend ratio by hand or setting up a sample slave-ratio controller to maintain the recipe. Trim control of rates during the run was a relatively simple matter. With the advent of several additional constraints upon the final product specification and availability of almost no new stocks for the planners, the problem of making both customers and regulators happy with the final product took on a new dimension. With several reductions in available degrees of freedom, the mathematical solution to this problem became a matter of a QP (quadratic programming) optimization problem, with the objective function being a residual sum of squares error on quality targets and optimal recipe targets. Without the use of high-quality analysis feedback and a multivariable controller (MVC), it would be nearly impossible for a refinery to blend Phase II fuels and stay in business for long.

5.3.2 Blend Run Set-up for Execution

The first thing that must be transmitted before a blend is configured is the blend summary, which contains approved blend entries downloaded to the blending system from a blend planning engineer. These recipes are based on optimized recipes run through a multiperiod optimizer (typically linear program (LP) with recursion or successive linear program iteration, called SLP) to handle the nonlinearities of predicting stock octane and assay blending. Most commercial systems have what might be

called a blend summary administration screen. The blend summary screen might display such minimum information as blend identification, finished product to be made (type, name, etc.), receiving tank, target volume, plus start and stop times.

Underneath the blend summary screen one should expect a blend entry screen which holds all the information needed functionally to define a blend. This would include one or more subdisplays for blend administration information plus the month/season for quality specifications to be met for this product, target volumes of feeds and product to be blended, receiving tank identifier and initial volume (heel) for finished product tank, percent of blend volume by which the finished product tank must meet specifications.

A more specific type of control screen is for blend recipe control. Information here would cover such items as components or additives to be used in a blend, primary source tank for feed component/additives, secondary component/additive source tanks to use in place of primary tank (if, perhaps, this tank runs low and approaches its minimum safe heel), component recipe percentages defined by the blend engineer, off-line optimizer results that are placed here when an off-line optimizer is run and its results are accepted, minimum and maximum component recipe percents, and other information needed by the blender operator.

Yet another screen typically separates feedstock control from final product control. Such a blend quality control screen allows the blend operator to specify or control the following: the finished product quality, blended product quality values as projected by the blend engineer to start the blend, minimum and maximum product specifications, blend move limits, constraints the quality should have a limit on; maximum (high) constraints, minimum (low) constraints, or should not limit at all (or let the optimizer use these limits), and finally blend header quality values, from the starting recipe to the final recipe projected by the off-line optimizer. Most blender systems also have text entry blocks that allow the operator to make comments to describe any special conditions of this blend, alarm summary statistics, automatic management report generation and routing, and so on.

Once the blend entry is defined and set up by the operator, equipment for flow control of the blend must be selected. The operator chooses the appropriate blend entry (from several that are being planned or that may be available for execution) for run preparation. A flow path must be chosen for each component tank. This path defines the pump(s) and meter(s)/flow controllers(s) to be used for this blend component. A default path is typically suggested by the system. This default path or another path may be used. The path flow limits are calculated for the pump/meter combination of the chosen loop. If the component flow rate required to achieve the blend rate is outside of the equipment flow limits, a message indicates this condition. The operator can choose a different loop or go ahead with this choice on the understanding that the necessary component flow cannot be reached.

A typical blend equipment selection screen displays the following: tank movement status (current flows into and out of the stock tanks), component/additive or finished product tank to be used in the blend, material in the tank, primary and secondary pump and flow meters used for component, product transfer for this particular loop, minimum and maximum limiting pump or meter flow rates, component/additive or finished product flow rate required for specified blend entry.

The basic blender control systems will stop here. The more sophisticated ones will include not only multivariable control functions but economic optimization control as well. This feature can be divided into two phases of operation, off-line and on-line optimization.

5.3.3 Off-line Recipe Blend Optimization[59]

After equipment has been selected for the blend entry, an off-line optimizer can be used to check the feasibility of the intended blend with actual current system values. Current tank qualities are used in the off-line optimization. The off-line optimizer is fundamentally the same as the on-line optimizer in that it uses the current rundown rates, tank inventories, and batch transfers in checking stock availability. This helps to find potential problems with the blend before the blender is actually started. If the product specification qualities cannot be met using the specified component recipe and constraints in the blend entry, the optimizer will give an infeasible result (and hopefully flags it to the operator as such!). This feature provides an important check on the validity of the refinery planning function where the original blend recipe originated. In a typical refinery, the planning group may not have access to all of, or even the same, information that the blend operator has.

The goal of an off-line optimizer is to find a recipe which primarily meets quality specifications for the product at or before the end of the blend, then secondarily reduces quality giveaway. The objective function is a minimization of recipe deviations and quality giveaway. Constraints for this optimization include final product quality constraints, recipe limits, path flow limits, and tank working volume limits.

An infeasible result means that the product quality specifications cannot be met with the components in the current recipe and the current path constraints. The constraints could be made less binding or the recipe could be changed. In any case, the limiting constraints will have

to be modified and the optimizer rerun until a feasible result is achieved.

If the results are feasible, the optimized recipe can be accepted into the blend entry, replacing the previous initial recipe used for the optimization. Off-line optimizers will typically show the blend engineer the following information: type of constraint encountered from beginning of blend to on-spec percentage of total blend, optimized component recipe from on-spec percentage of total blend to end of blend, optimizer result – infeasible or feasible, optimized quality value at both the blend header and receiving tank when on-spec percentage is reached and when end of blend is achieved, path flow limits and infeasibilities, and stock tank conditions at end of blend. Finally, there needs to be a means of accepting the results (basically a yes or no answer.) A feasible result only should be accepted for download into the blender distributed control system (DCS).

5.3.4 Blend Run Initialization, Launch and Monitoring

When the results of the off-line optimizer are satisfactory, the blend entry information can be passed to the header quality control function and downloaded to the DCS to initialize the blender. The recipes, quality targets, and most blend entry information are passed on to the DCS. Recipe and quality targets are passed to the header multivariable controller (MVC) quality controller. The blend entry is then executed from the DCS. After the blend is started and operating near full flow rate, on-line optimization and header quality control can be activated.

Figure 6 shows a schematic of an MVC based CARB blender package.

During the blend, header qualities are monitored by intermittent on-line analyzers, calculated, and manually entered data. The analyzer values are available through the DCS. For every on-line analyzer, a good/bad status is needed to indicate whether the value is useful for control. For each analyzer, a status is required to indicate when a new result is available.

A well-designed blend launch and monitoring screen displays the standard blend identifier information plus header and predicted tank qualities in real time, analyzer status (good/bad) and results along with ongoing predictions of header qualities, real-time tank movement data, updated laboratory results, and alarm messages for problems and constraints encountered during the run. For US EPA Phase II or CARB specification blending, a multivariable advanced controller is essentially a necessity. The operators should always be able to see the status of

Figure 6 Multivariable blender control (PLC = programmable logic controller).

the MVC unit and the metrics by which its control can be judged.

Figure 7 shows a typical control strategy that typically might be used on a CARB blend recipe. Only three control variables (CVs) are targeted and only a total of seven are available with the stocks available to the blender in this case. Controlling the T10 and the RVP simultaneously, in fact, often poses control problems. If this happens, one or the other criteria must be relaxed somewhat. In typical MVC systems, a two sided control range is an indication that a quality has a regulatory (usually maximum) constraint and a set of economic criteria (if not exactly constraints) or performance quality constraints which are usually the determinants of the lower control constraints. Such conflicting goals are the reason that MVC is essential in making CARB or Phase II gasolines.

Figure 8 shows the essential monitoring function that a quality controller must be able to perform. The final

Figure 7 Blend target strategies. Overall design objective is to maximize degrees of freedom to create a blend that meets multiple specification, leading to (a) target and constraint variables versus (b) constraint only (zone) variables.

Figure 8 Monitoring the blending system for performance (CPI = chemical process industries).

tank or target pipeline specification must continually be examined for predicted to measured accuracy and corrective action taken if discrepancies occur, including shutdown reoptimization of the recipe and restart of the blend process.

5.3.5 On-line Blend Optimization[59–62]

As the blend run proceeds, the controller varies the signals sent to the individual component flow loop controllers based on the multitude of information received from flow meters, pump motor power meters, analyzers, temperature and pressure indicators and perhaps a parallel predictive or ''virtual'' model of the blend properties as well. The MVC tries basically to minimize the deviation of all flow rates from the specified setpoints. All controller output moves that it makes come from the multivariate nature of the blend problem with competing specifications and quality needs that require constant give and take in order to minimize the deviation from the target of any one quality in the final blend.

Most MVC installations control a combination of predicted qualities modified by regularly updated analyzer values during the course of the run. For whatever reasons, the predicted and measured qualities will diverge to some extent. Occasionally this divergence is significant. In such cases, with the MVC package and being constantly mindful of constraints and competing quality requirements, the blend is still quite feasible but may no longer be as economical as possible. An on-line optimizer provides the blend operator with a chance to redefine the remainder of a blend recipe based on a set of economic and operating criteria.

The result of an on-line optimizer is a new set of setpoint targets. Generally, on-line optimizers will run every 2–10 min, constantly reexamining the ''optimal blend'' problem based upon what has already been passed through the blend header and what is still left in the stock tanks, all the while heeding the same quality specifications and process constraints that govern the MVC. When the new ''optimal'' and current setpoints differ to some significant amount, the on-line optimizer will flag the condition and suggest that the blend operator makes a move. Usually the new setpoints end up being the ideal resting values (IRVs) for the MVC as it wrestles with the multiple specification problem it must satisfy. Making these IRVs the new setpoints will usually make the MVCs job easier and the control of the blend becomes quite stable in operation. Every once in a while, a well-designed on-line optimizer will recognize money-making opportunities such as the opportunity to blend more butane or high RVP straight run naphtha into a blend that is otherwise heading towards a serious RVP ''giveaway'' situation.

6 FUELS ANALYSIS FOR REGULATORY REQUIRMENTS[11,23,31,53,63,64]

6.1 Introduction

The technology available for the chemical and physical characterization of petroleum and chemical feeds and products has improved steadily. Better detectors and better electronics have resulted in higher sensitivity and speed of analysis for many of the more well-established techniques. At the same time, new scientific concepts and the availability of low-cost minicomputers have resulted in the creation of new techniques that provide novel information. The integration of the information from these new, and often extremely expensive, instruments results in a remarkably detailed knowledge of the composition of various process and product streams, particularly when the various separation processes are appropriately combined with the other instrumentation. The following sections provide a brief summary of the more commonly used techniques available today, together with a number of basic references that provide a more detailed discussion of both the scientific principles and areas of application for each system.

6.2 Analytical Procedures – Component Separation Methods[1,3,56,65–68]

Petroleum streams and chemical feedstocks are usually quite complex mixtures and the analysis of these systems can frequently be simplified through some form of prior separation. The separation techniques commonly employed are distillation, to narrow the boiling range, and chromatography, which provides both boiling range and compound-type separations. Much of the recent progress in obtaining more detailed compositional data on petroleum and chemical streams can be attributed to the wide use of chromatography. Such separation techniques are also used to isolate pure compounds or compound types needed as calibration standards for the instrumental methods describe later.

6.2.1 Distillation

Distillation tests are generally performed on products destined to be used under conditions involving conversion to the vapor state. Thus, the distillation characteristics of all fuels are important quality considerations. Since solvent quality depends on the rate of evaporation, distillation characteristics are also important for this type of product. In the case of heavier products such as lubricating oils, distillation is carried out under reduced pressure to avoid cracking. Here distillation characteristics are useful in predicting oil consumption in automotive crankcases in certain types of automotive service.

Distillations are reported in one or more of the following terms:

1. IBP
2. distillation temperatures for increments of volume overhead
3. percent evaporated at specific temperatures
4. EP or maximum temperature
5. dry point
6. recovery or loss
7. residue.

Five standard laboratory procedures for distillation of petroleum-based fuels have been standardized. Three are run at atmospheric pressure and one at reduced pressure. Four of the atmospheric methods, D-86, D-216, D-285, and D-1078 are of a type that results in a very modest degree of fractionation effected by a minimal reflux of the distillate in the neck of the flask. The method at reduced pressure, D-1160, is designed to attain fractionation equivalent to about one theoretical plate. A gas chromatographic (GC) method, D-2887, is now available. It is roughly equivalent to D-86 but requires some conversion of the raw data. D-216 is little used now, as the naphtha fractions from current gas plant liquids recovery almost always goes through a stabilization process designed to fit certain D86 cut requirements.

Table 10 shows the standardized distillation procedures for the various types of petroleum products.

Briefly, the distillation procedure consists of heating a sample in a flask fitted with a thermometer, and then causing the vaporized portions to pass through a tube condenser which extends through an ice–water bath and into a glass cylinder graduated in milliliters. Readings show the amount of sample evaporated at a given temperature. A diagram of a basic laboratory apparatus for D86 analysis is shown in Figure 9.

When the first drop falls from the end of the condenser, the reading of the distillation thermometer is recorded as the IBP. The heating of the sample continues at a uniform rate and the volume of distillate collected in the cylinder is observed and recorded to the nearest 0.5 mL, as the thermometer reaches each multiple of 10 °C, or the temperature is recorded when the distillate level reaches each 10-mL mark on the graduate. The EP or FBP is the highest

Table 10 Distillation procedures

Type of product	ASTM specification
Gasoline, naphtha, kerosine	D-86, D-3710
Gas oil, distillate fuels	D-86, D-1160, D-2887
Natural gasoline	D-216, D-3710
Solvents and diluents	D-1078, D-3710
Heavier products (reduced pressure)	D-1160, D-2887

Figure 9 Conventional D86 apparatus.

temperature observed, which is usually reached just as the flask bottom has become dry. Appropriate corrections to the results are made for evaporation loss and barometric pressure. In manual mode, the ASTM distillation procedures require a substantial amount from the laboratory technician. Fortunately, several vendors have made modifications to the apparatus of Figure 9 which automate the heating and volume–temperature accounting process. It should also be noted that the initial and FBPs are somewhat subjective in nature and are, therefore, the least accurate points of the entire assay curve.

All distillation procedures are designed to give results which throw some light on the suitability of the various products for their particular use. All these procedures cannot be described in detail or the significance of their results discussed in this text. However, the quality of motor gasolines as judged from distillation data is presented as being typical of the use of distillation characteristics. Of these procedures, D86 is probably the leading standard. Several methods of measuring volatility via alternative methods, primarily gas chromatography (GC), have come into wide use but they all have the common denominator of requiring calibration standards set by the D86 standard.

6.2.2 Chromatography

As either a separation or as an analytical technique, chromatography[52,66] may be conveniently divided into two categories: GC, and liquid chromatography (LC).

It has been generally found that LC complements GC as a separation tool in the laboratory. LC is ideally suited to samples that are nonvolatile or are sensitive to heat. It generally separates on the basis of compound type. In contrast, GC separates partly on polarity and partly on the basis of volatility, and therefore molecular weight has an influence on the separation. If one employs a special packing in LC, such as a cross-linked polymer with a controlled pore size, separation according to molecular size can be achieved. This is called gel permeation chromatography (GPC). This technique is especially valuable for the determination of molecular weight distribution in polymers and resins.

Here are some additional standards that may be applicable in chromatographic analysis of regulated fuel components.

- ASTM-F1374 – Ionic/organic Extractables of Internal Surfaces-LC/GC/FTIR (Fourier transform infrared) for Gas Distribution System
- ASTM-E1642 – General Techniques of Gas Chromatography Infrared (GC/IR) Analysis, Standard Practice
- ASTM D-3710 – Boiling Range Distribution of Gasoline and Gasoline Fractions by Gas Chromatography, Standard Practice
- Also ASTM D-3710, D-2427, ASTM F-1374, D3606, and D4815 have pertinent sections that apply to chromatographic methods.

6.2.2.1 Gas Chromatography Since its commercial inception in the 1950s, GC[69] has had astronomical growth in analytical laboratories. The ease of use and versatility of the equipment has allowed gas chromatographs to be used for process as well as laboratory bench instruments.

Basically, GC is a simple technique. A typical GC schematic is shown in Figure 10. A sample is injected onto a column through which a carrier gas is flowing. A typical sample size for a liquid is of the order of a microliter; for a gas, a few milliliters. Liquid samples are vaporized in a heated injection block located ahead of the column. Some solid samples can be handled by using a special solid inlet system. The column is the heart of any chromatographic separation and may take any one of a number of forms. It is either a stainless-steel tube, about 3-mm inner diameter, packed with an inert solid coated uniformly with a liquid of low volatility, or a capillary tube, about 0.3-mm inner diameter, whose interior wall is coated with the liquid. As the sample is carried along by the gas, separation occurs by differential partitioning between the gas and the liquid coating. A large choice of liquid substrates is available, so

Figure 10 Basic GC schematic.

that the selectivity of the column may be matched to the mixture to be separated. The length of the column may vary from several centimeters for packed columns up to a hundred meters for the capillary. The column is housed in a temperature-controlled oven, the temperature of which can be increased according to a preset program. This had the advantages of either shortening the analysis time or improving the separation, or both.

As sample components are eluted from the column, they are sensed by a detector, the signals from which are recorded. The intensity of the signal is a quantitative representation of the amount of each component. There are a variety of detectors to ensure proper detection of the compounds of interest from the standard hydrocarbon analysis, such as sulfur, nitrogen, halogen and organometallics. Some are general purpose detectors, e.g. thermal conductivity or flame ionization, the latter having essentially equal sensitivity to all hydrocarbons. Others are sensitive to specific elements or compound types. For example, microcoulometers have been used to detect sulfur- and nitrogen-containing compounds in gas oils and other petroleum fractions, while electron capture detectors are highly sensitive to halogens and aromatics. Gas chromatographs have been successfully coupled to the more exotic mass spectrophotometers, Fourier transform infrared (FTIR) and atomic emission spectrum (AE) detectors.

GC is used to characterize a wide variety of hydrocarbon samples. Identification and measurement of the 500 or more components in gasoline are made routinely by GC. For analyses such as these, identification of the components eluting from the column is made by comparing their retention times to the retention times of reference materials, using carefully reproduced chromatographic conditions (column, temperature, flow rate, etc.).

This speciation process is necessarily a slow procedure which usually requires several hours. By contrast, GC distillation data are obtained in much less time, usually one hour or less. If the chromatograph is part of an automatic data handling system, a continuous curve of temperature vs percent overhead can be printed out by a computer-controlled plotter.

Column selection has been expanded to include capillary columns, meaning that the need for knowledge in selecting the right column is important. Capillary columns give the chromatographer the capability successfully to measure compounds that were difficult to measure in the packed column days.

While this new equipment has been developed to enable users to make measurements more accurately and faster at lower detection levels, a whole new set of problems arise with sample and data handling techniques used with new equipment. The trade-off of this new high-tech capability is the need for highly exacting techniques for handling the samples. Since smaller and smaller quantities of material are needed for the analysis, the significance of small levels of contamination becomes magnified. The quantities of material being injected are a

fraction of what they were during the packed column days. Sample sizes were large enough to overcome cross-contamination from a poorly flushed injection valve. Today, one must be concerned about micro levels of cross-contamination, sample cleanliness and sample volumes.

The smaller sample quantities compound the effect of contamination in several ways. From the use of syringes to the use of sampling valves for injection, attention to the sample preparation has become paramount to the analysis, second only to the method/application being used to measure the components of interest. The systems used to introduce the samples have also undergone a radical transition. Many of the new systems are capable of detecting very low quantities of components in a very short time.

Analytical expectations also are different now. In 1980 or even by 1990, refiners were concerned about percent and parts per million levels of detection. Now they are faced with lower levels of detection, parts per million, parts per billion and even parts per trillion levels, with coincident delivery of results in real time.[69]

6.2.2.2 Liquid Chromatography LC has undergone a radical change. The analysis time has been shortened from hours to minutes and the efficiency of the columns has been increased to several thousand theoretical plates per foot. This has been made possible primarily because of the advent of new high-pressure pumps and small-diameter packing materials for columns.

The schematic shown in Figure 10 is equally applicable to LC and GC by replacing the gas elutriant with a liquid one. Between 1–20 μL of a solution of the sample are injected onto a packed column through which a liquid is flowing under pressure. The pressure, which may be up to 40 MPa is needed to achieve adequate flow rates; up to 5 $cm^3\,min^{-1}$. The injection block and column are usually maintained at ambient temperature. The column may be packed with a solid such as silica gel, forming a ''liquid–solid'' chromatograph. This solid may be modified by adding a liquid coating, which may or may not be chemically bonded to the surface, resulting in a ''liquid–liquid'' chromatograph. Separation is achieved by differential partitioning between the moving liquid phase and the stationary solid or liquid phase. The flowing liquid plays an active role in the separation process, and its choice, together with that of the stationary phase, determines the selectivity of the column. To shorten analysis time and to improve resolution, the composition of the moving phase can be changed as the analysis progresses. This is called solvent programming and is analogous to temperature programming in GC.

As the components are eluted from the column, they are sensed by a detector, two types of which are used most commonly. One type, the refractometer, senses a change in the refractive index of the solution and is a general detector, i.e. it will sense any component eluting from the column as long as its refractive index differs from that of the solvent. A second type is a visible range or UV spectrophotometer, and is specific for materials that absorb in a preselected part of the spectrum.

Several LC methods are now used – medium pressure, high-performance liquid chromatography (HPLC), and thin layer methods being the more popular test procedures. They mainly are used on diesel stocks, often to determine aromatics. The calibration techniques to do this are fairly rigorous, and, to date, few standards apply for regulatory purposes.

6.3 Electromagnetic Field Spectroscopy[20,63,67,68,70,71]

6.3.1 General

Electromagnetic field (EMF) spectroscopy is the science of measuring the absorption and emission by atoms and molecules of electromagnetic radiation and of interpreting the results in terms of the composition and structure of such materials. As described in the following sections, spectroscopy can be subdivided into a number of separate fields of endeavor, each related to the various subsections into which the electromagnetic spectrum is commonly divided. The different fields yield different information on the structure and composition of both organic and inorganic materials and between them they are capable of providing a great deal of analytical information of importance to the following and understanding of petroleum and chemical processes. Quantitative spectrophotometric analyses can be accomplished by using Beer's law (Equation 1), where

$$I = \frac{I_0}{I} \quad \text{or} \quad A = abc = \frac{\log I_0}{I} \tag{1}$$

where I is the intensity of the radiation of a given frequency falling upon the sample, I_0 is the intensity transmitted through the thickness b (in cm) of the sample. The zero subscript refers to the transmission of the standard solution at a known calibration value, c is the concentration of the sample (g^{-1}) in the thickness b, and a is the absorptivity or absorbance of the sample, a constant for a material at a given frequency.

The absorbance is more simply related to the concentration and absorptivity than is I and so is therefore commonly employed for quantitative analysis. The ratio I/I_0 is the percentage of radiation transmitted and is commonly known as transmittance, T.

6.3.2 Infrared Spectroscopy

Infrared (IR) absorption spectroscopy,[72,73] covers generally that part of the electromagnetic spectrum between

about 10 000 and 50 Hz (1–200 μm), though in practice the bulk of the work is somewhere between 4000 and 200 Hz (2.5–50 μm) in what is referred to as the near-infrared (NIR). The energy of the radiation in this region of the spectrum corresponds to the energy range characteristic of molecular vibrations, and such radiant energy can be absorbed by resonance interaction. A plot of the amount of energy absorbed vs. the frequency of that energy results in a complex spectrum that is unique to the absorbing molecule. Large catalogs of spectra of pure compounds exist and so it is relatively straightforward to identify an unknown material by comparing its IR spectrum with that of known reference compounds. It is also found that similar chemical structures absorb in a characteristic and relatively small range within the overall spectrum; for example, all carbonyl groups, $>C\cdots O$, absorb in the region 1650–1800 Hz. Therefore, the presence or absence of such functional groups as ketones, alcohols, esters, carbonates, nitriles, and so on, can readily be determined in pure compounds or complex mixtures, both organic and inorganic. Such mixtures may be solids, liquids, or gases.

IR spectroscopy is widely used for the identification of unknown compounds or materials and for the components in many complex mixtures. It can be used to determine the structure of organic and inorganic compounds and to determine both the structure and conformation of polymers. It can also be used quantitatively for the analysis of, for instance, additives in lube oils, copolymer compositions and aromaticity.

6.3.2.1 Fourier Transform Infrared Analysis FTIR technology,[74] one of many flavors of IR spectroscopy, is perhaps the most widely used methodology aside from GC for on-line analysis of hydrocarbons. An FTIR unit typically operates by continuously extracting a sample that is filtered, pressure-regulated, and temperature-controlled in the sample system cabinet. All three of these operations are critical to accuracy. The sampling system must also be responsible for introducing reference samples, wash solvents and sample cell purging.

The analysis is performed by measuring the absorption caused by the compounds as the IR beam passes through the sample cell. The absorption in any one unique frequency is proportional to the concentration of the components in the sample, but with a mixed sample, several different frequency responses may be received additively or may cancel each other via wave physics. The system computer receives the detector signal and simultaneously records an interferogram from the hundreds of spectral patterns it gets. At the end of the test, the computer recalculates the original spectra using fast Fourier transform (FFT) mathematics, a decades old signal processing technology that has become popular with the advent of personal computers and benchtop workstations. The computer then reports the revised component type analysis (from its reference sample database) and component concentrations in standard engineering or scientific units.

6.3.3 Ultraviolet/Visible Spectroscopy

UV/visible absorption spectroscopy[71] covers that region of the spectrum between 195 and 1000 nm. Absorption of energy in this region by molecules results in transitions between electronic states and, as with IR spectroscopy, such a spectrum can be used to provide information on the structure and composition of a sample. The most valuable analytical information from a petroleum and chemical processing point of view is obtained on molecules containing highly conjugated systems, particularly aromatic hydrocarbons and conjugated olefins, because such molecules have characteristic spectra and very high absorptivities.

UV/visible spectroscopy is the most powerful method for identifying and measuring trace (ppm–ppb) quantities of PNA hydrocarbons in hydrocarbon systems, particularly in combination with GC and other separation techniques.

6.3.3.1 Fluorescent Indicator Adsorption Fluorescent indicator adsorption (FIA) technology is the most widely used methodology aside from GC for on-line analysis of hydrocarbons with multiple carbon–carbon bonds such as olefins and aromatics. FIA has been an ASTM standard for over 40 years, first appearing as such in 1954, so it is well known and established. It is inexpensive to implement in spite of the fact that it is still a laboratory based manual method. FIA determines the relative amounts of saturates, olefins and aromatics well enough to often substitute for some of the more expensive PIANO testing equipment mentioned in this section. Even so, there has been some controversy about its use for regulatory olefins emissions analysis.

A FIA unit operation is based on the separation of hydrocarbon components according to their adsorption affinities on activated silica gel. A sample is introduced onto the top of a bed of silica gel and packed in a glass column of small, uniform diameter. Isopropyl alcohol is added to desorb the sample and force it down the column. The components with the least affinity for silica gel are the saturates, which move to the front of a traveling band of sample. Those with progressively higher affinities (olefins and aromatics) lag behind.

Fluorescent dyes, visible under UV light mark the zonal boundaries of the saturates, olefins, and aromatics. The amount of each hydrocarbon type, in volume %, is calculated from the length of the zone. Because the fluorescing bands have a measurable length, which can be significant relative to the zone length of a particular hydrocarbon component, differences in ''reading'' the position of the boundary add a source of potential error to the determination.

The presence of significant C_4 and C_5 volatiles in gasoline leads to low-olefin readings compared to other PIANO-type analyses on the same sample composition. A note warning of this possibility appears in the ASTM D-1319 standard which also states that samples containing more than 5% C_4s or 10% C_4s + C_5s should be dependentanized prior to analysis. This extra distillation step does not help the reproducibility of the method.

The author also has had trouble with FIA results for high-olefin stocks such as catalytic gasoline which will routinely contain 25–50% olefins. Any values above 30–35% give FIA readings that are suspect at best.

Here are some additional standards that may be applicable for use of UV spectrophotometry analysis of regulated fuel components:

- ASTM D-1840 – Naphthalene Hydrocarbons in Aviation Turbine Fuels by Ultraviolet Spectrophotometry, Standard Practice.
- ASTM D-1017 – Benzene and Toluene in 250 F and Lighter Petroleum Products by Ultraviolet Spectrophotometry.

6.3.4 Nuclear Magnetic Resonance Spectroscopy

Nuclear magnetic resonance (NMR) is a form of radiofrequency spectrometry which uses the weak magnetic properties of atomic nuclei that possess nuclear magnetic moments. The most notable nuclei for petroleum characterization are H and C, the latter of which is only 1% abundant in nature. In the presence of a strong applied magnetic field the nuclear magnetic dipoles have certain preferred orientations, or energy levels, the energy separation of which is directly proportional to the *total* magnetic field sensed by the nuclei. The total magnetic field is the sum of the large applied field and very small molecular magnetic fields which are sensitive to the details of the environment of each nucleus. At a fixed applied magnetic field, chemically distinct nuclei will absorb at slightly different radiofrequencies. These small differences in absorption frequency are referred to as *chemical shifts*. Interaction between nearby magnetically nonequivalent nuclei may result in multiple absorption peaks for the particular nucleus affected. The number of peaks observed and the spacing between them varies in a predictable manner and is referred to as the *spin–spin splitting* pattern.

Both the chemical shift and the spin–spin splitting pattern are useful for determining molecular structures. A third important feature of NMR spectra is that the relative areas of the absorption signals of the various nuclei are proportional to the number of nuclei giving rise to the NMR signals. Thus, quantitative measurements are made by integrating the area under the signals, or peaks, which are due to different groups.

Proton (H) NMR is rapid and nondestructive. It has long been a useful ally of GC and mass spectrometry for characterization of volatile petroleum fractions. Determination of olefin type and the degree of branching in saturated side chains are typical applications. Proton NMR has the additional advantage of being applicable to high-boiling fractions and residues.

Developments in NMR techniques have made C NMR a practical reality. Carbon-13 NMR is difficult because the magnetic isotope (C13) is only 1% of the naturally occurring isotopes of carbon. The great advantage of C13 NMR is its much greater chemical shift range (100 times that of proton NMR). Moreover, C13 NMR probes the carbon skeleton directly, rather than inferring this information via the protons in the molecule. The result is that C13 NMR is many times more powerful than H NMR for characterization of complex hydrocarbons. Carbon-13 NMR provides a direct determination of aromaticity (% aromatic carbon), degree of aromatic substitution, and has the potential to provide a detailed analysis of side chain structure (average chain length, branching, etc.). Exploration of the full potential of C13 NMR for petroleum characterization is an active area of research.

Some ASTM standards for specific component analysis are:

- D-2622, D-4294 for sulfur in petroleum stocks,
- D-4059 for lead in petroleum stocks,
- D-3701, D-4808 for hydrogen content in petroleum stocks.

6.3.5 Emission Spectroscopy[70]

When the atoms of a material are subjected to an electric arc, spark, or hot flame, electrons in the atoms are excited to energy levels higher than the ground state. When these electrons lose their excitation energy, light is emitted in the UV and visible region of the spectra. The electronic transitions involved are discrete so that a set of spectral lines is produced which is characteristic of the emitting atom. Furthermore, the intensity of the spectral lines is proportional to the number of emitting atoms. Thus, the emission spectrum can be used both to identify which elements are present in a material and to measure the concentration of the various elements. Quantitative work does, however, require that suitable standards be available for comparison.

The essential components of an emission spectrograph include (1) a radiation source, (2) an optical analyzer, and (3) a detector.

The radiation source includes the sample to be analyzed and a means of excitation such as the electric arc or spark. With these forms of excitation an electrical current is passed between two electrodes either as a continuous arc or as a spark. If the sample is a metal, the sample itself can serve as one or both electrodes. For other types of sample carbon electrodes are generally used to contain the sample during excitation. The actual design of the electrode will depend on the form of the sample and the elements of primary concern. Both liquid and solid samples can be analyzed.

The optical analyzer serves two functions in the spectrographic system. It provides a sharp image of the radiation emitted from the excited source, and it separates the radiation into its component wavelengths. The focusing required to produce a sharp image of the source is accomplished with lens or focusing mirrors. The spatial separation of the light as a function of wavelength is accomplished with a diffraction grating; a flat piece of glass, metal or plastic on which are ruled a large number of parallel grooves (6000–10 000 grooves per centimeter).

The detection of the dispersed radiation is generally accomplished with a photographic plate or a photoelectric detector. Photographic plates are generally used for qualitative work because a wide range of wavelengths can be recorded simultaneously. The analysis of an unknown spectrum is accomplished by comparing it to reference spectra of known elements. Quantitative analysis is generally performed on instruments which utilize photoelectric detection. In practice, instruments designed for quantitative analysis often have a number of photoelectric detectors (up to 48) which can be set for different wavelengths. It is thus possible to perform simultaneous multielement determinations with this type of equipment. In principle, every element in the periodic table can be detected by emission spectroscopy, but it is routinely useful with approximately 70 elements. Qualitative analysis data can be obtained on as little as 0.1 mg of a solid sample, and under favorable conditions concentrations down to a few parts per billion can be determined. The technique is used extensively in such problems as the analysis of wear metals in lube oils, qualitative analysis of corrosion products, and the determination of catalyst impurities.

6.3.5.1 Flame Ionization Detection This is probably the most common emissions spectroscopic method used for hydrocarbon analysis. Most commercial implementations have excellent sensitivity and stability at parts per

million levels of detection, even in harsh process conditions. Since sample flow, flame and temperatures are constantly monitored, maintenance and error detection are greatly simplified. FIDs (flame ionization detections) are easily automated and pair well with elution-type analyzers such as a GC.

The analyzer operates by burning the sample (vaporized) in a hydrogen-based flame. The hydrocarbons present are ionized in the flame and have the ability to conduct electricity through the flame to a collection grid surrounding the flame. By applying a high-voltage charge to the flame tip, the hydrocarbons in the sample can be measured by monitoring the current reaching the collection grid. This technique is not only sensitive to general hydrocarbons but those with easily oxidized heteroatoms as well – sulfur, chlorine, and so on.

Here are some more standards that may be applicable in emission spectroscopic analysis of regulated fuel components:

- ASTM D-3605 – Trace Metals in Gas Turbine Fuels by Atomic Absorption and Flame Emission Spectroscopy
- ASTM-E115 – Photographic Processing in Optical Emission Spectrographic Analysis, Standard Practice.

6.3.6 Atomic Absorption Spectroscopy

Atomic absorption spectroscopy, a technique related to emission spectroscopy, is used to measure the concentration of a wide range of metallic elements. In this technique, a sample is vaporized in a flame or on a carbon rod and the vapor is irradiated by a lamp which has a cathode made from the element being sought. Electrons in the ground state atoms produced by the flame absorb the resonance lines emitted by the lamp and are thus excited to a higher energy level. The amount of energy absorbed, measured using a photodetector, is related to the concentration of the element present in the sample. The usual operating range of the method is from less than 1 ppm to about 100 ppm.

Some particular applications to the industry include the determination of metals in crude and refined products, in the additives in lube oils, and in aqueous systems such as effluent waters.

Here are some more standards that may be applicable in atomic absorption spectroscopic analysis of regulated fuel components:

- ASTM D-3605 – Trace Metals in Gas Turbine Fuels by Atomic Absorption & Flame Emission Spectroscopy,
- ASTM-E885 – Analyses of Metals in Refuse-derived Fuel by Atomic Absorption Spectroscopy, Standard T
- ASTM-E924 – Quality Assurance of Laboratories Using Molecular Spectroscopy, Standard Guideline for
- ASTM-E863 – Describing Flame Atomic Absorption Spectroscopy Equipment, Standard Practice for
- ASTM D-3237 – Lead in Gasoline by Atomic Absorption Spectroscopy, Standard Test Method for
- ASTM D-4053 – Benzene in Motor and Aviation Gasoline by Infrared Spectroscopy, Standard Test Method for
- ASTM D-3831 – Manganese in Gasoline by Atomic Absorption Spectrometry, Standard Test Method for
- ASTM-E131 – Molecular Spectroscopy, Standard Terminology Relating to

6.3.7 X-ray Analysis Techniques

X-rays are produced when fast-moving electrons, or other X-rays, interact with the atoms of a target material. The primary mechanism of the interaction involves displacement of an inner electron from an atom, followed by the ''falling'' of an outer electron into the resultant hole. An X-ray photon, whose energy is the difference between the energies of the inner and outer electrons, is produced. Electron energies differ from element to element, and so the emitted X-ray energy is characteristic of the atom from which is was generated. Since atoms contain many different electrons, a number of characteristic X-ray energies are associated with each element.

In addition to the characteristic X-ray spectrum of a material, a continuous spectrum is also produced. This is due to a loss of energy when an electron interacts with the strong electric field of an atomic nucleus. This energy loss appears as an X-ray photon. The energies of the X-rays produced by this mechanism are independent of the nature of the atoms being bombarded and appear as a band of X-rays of continuously varying energy.

X-rays are characterized by either their wavelength or their energy. Equation (2) relates the two quantities

$$\text{change in energy} = \frac{hc}{\text{wavelength}} \tag{2}$$

where h is Planck's constant and c is the speed of light.

The X-ray region of the electromagnetic spectrum covers a range from 0.02 Å to slightly over 100 Å (1 Å $= 10^{-10}$ m). The use of X-rays with wavelengths larger than about 2.5 Å, however, requires special vacuum techniques to minimize photon losses caused by air absorption.

There are three different X-ray techniques used for analysis: diffraction, fluorescence (emission) and absorption. X-ray diffraction is used most in analysis of solid crystalline structures and will not be discussed further in this article.

6.3.7.1 X-ray Fluorescence The characteristic radiation produced when a material is bombarded with X-rays or electrons can be used to identify which elements are present in the material and to measure the concentrations of the various elements. The identification of unknown elements in a sample is based on comparing the wavelengths or energies of the observed X-rays to the known values for the elements in the periodic table. The concentrations of the elements are determined by measuring the intensities of the characteristic X-rays and comparing these to the measured X-ray intensities in suitable standards. In practice, the technique is generally limited to elements with a greater atomic number than 11 (sodium). It is often called chemiluminescence.

X-ray fluorescence instrumentation may be classified as either wavelength dispersive or energy dispersive. Wavelength dispersive systems employ a single crystal which separates the various characteristic X-rays by diffraction according to Bragg's law. The resulting diffracted X-rays are detected by a scintillation counter or flow proportional counter. Because X-rays with different wavelengths are spatially separated, measurements in a multielement system are conducted sequentially. Energy dispersive systems utilize a solid-state detector which is capable of both counting the number of incident X-rays and sorting them according to energy. Since information on all elements in a sample is received simultaneously, a device like a computer is needed to store the information. In general, multielement analyses are conducted more rapidly with an energy dispersive system. Furthermore, for most energies,the resolution of a wavelength dispersive system is superior to that of an energy dispersive system.

Elemental analysis on both liquid and solid samples can be carried out by X-ray fluorescence. The optimum concentration range for analysis is generally down to about $1\,\mathrm{mg\,g^{-1}}$. In many cases, however, concentrations as low as a few micrograms per gram can be determined without great difficulty. The major experimental requirement for elemental analysis by X-ray fluorescence is that standards which match the composition of the samples of interest be available for instrument calibration. A variety of sample preparation and measurement techniques have been developed to meet this requirement. The most recent developments in this area include the use of various mathematical techniques to correct measured intensities for changes in the sample matrix. The successful application of these techniques greatly minimizes the amount of sample preparation required.

Some of the major applications of X-ray fluorescence include the determination of metals in catalysts, the determination of trace metals in cracking feedstocks, the determination of lead and sulfur in petroleum fuels, and the determination of additive components in lubricants.

A derivative method involves the bombardment of material with neutrons and measurement of the X-ray spectra emitted. This method is used in some on-line flow measurements.

6.3.7.2 X-ray Absorption The third X-ray technique used for analysis is X-ray absorption. All materials absorb X-rays, some more than others. The relationship which governs the absorption process is the Beer–Lambert law, Equation (3)

$$I = I_o e^{upt} \tag{3}$$

where t is the thickness of the absorber, p is the density of the absorber, u is its mass absorption coefficient and I and I_o are the transmitted and incident X-ray intensities. u is a function of both the elemental composition of the absorber and X-ray wavelength or wavelengths used. At fixed wavelength, the mass absorption coefficient can be expressed in terms of the elemental composition of the absorber in the following manner, Equation (4)

$$u = \sum u_i W_i \tag{4}$$

where u_i is the mass absorption coefficient of the ith element in the sample and W_i is its corresponding weight fraction.

From this it is clear that a measurement of the transmittance (I/I_o) is not sufficient to determine the concentration of all I elements in a sample. Good results can be obtained, however, in specific applications where only one component of a sample is varying, where all other components are comparatively weak absorbers, and where any change in density of the sample is due to the variation in the one component. In such cases the transmittance of the sample at fixed thickness can be calibrated in terms of the weight concentration of the varying component. This technique is well suited, for example, to the continuous monitoring of TEL metals or sulfur in gasoline or in a hydrocarbon matrix.

Here are some additional standards that may be applicable in the use of X-ray analysis of regulated fuel components:

- ASTM D-2599 – Lead in Gasoline by X-ray Spectrometry, Standard Test Method for
- ASTM D-3229 – Low Levels of Lead in Gasoline by Wavelength Dispersive X-ray Spectrometry, Standard Test Method

- ASTM D-2622 – Sulfur in Petroleum Products by X-ray Spectrometry, Standard Test Method for
- ASTM D-4294 – Sulfur in Petroleum Products by Energy-dispersive X-ray Fluorescence Spectroscopy, Standard Practice for
- ASTM-E1015 – Reporting Spectra in X-ray Photoelectron Spectroscopy, Standard Practice for
- ASTM-E1508 – Quantitative Analysis by Energy-dispersive Spectroscopy, Standard Guide for
- ASTM D-5059 – Lead in Gasoline by X-ray Spectroscopy, Standard Test Methods for

6.4 Mass Spectrometry

The mass spectrometer is a most useful analytical tool in petroleum laboratories. This is due to the availability of good commercial instruments and to the capability of mass spectrometry to analyze complex mixtures rapidly and accurately.

The basic principles of mass spectrometry are simple. A sample is allowed to evaporate into a reservoir at about 47×10^{-4} kPa. It then enters the mass tube through a small leak or orifice, the pressure in the mass tube being maintained at between 1.3×10^{-47} kPa (no sample) and 1.3×10^{-46} kPa (with sample). A small proportion (about 0.2%) of the atoms are ionized by electrons emitted from a hot tungsten filament. This ''electron gun'' creates 70-V energy electrons. The ions ''crack'' into charged fragments and these fragments are accelerated through the mass tube in a magnetic field. The ion paths are altered by the magnetic field in direct relation to their mass, the path of a low mass ion being bent more than that of a high mass ion. By varying either the magnetic field or the accelerating voltage in a continuous manner, one mass at a time passes through the exit slit of the mass tube to the collector plate. After amplification, a mass spectrum of mass numbers vs currents is recorded. The fragmentation pattern of a compound serves to identify the components present in the sample.

Mass spectrometry is applied to the analysis of gases, liquids, and solids. This technique requires about a microliter of liquid sample and a few milliliters of gas, at atmospheric pressure, for analysis. Quantitative determination of complex mixtures can be achieved by proper selection of analytical points (mass/charge) for the compounds present and setting up and solving the sets of simultaneous equations obtained.

One application of mass spectrometry in the petroleum field is for the analysis of gaseous mixtures. Mixtures containing 20 or more components can readily be analyzed. Examples include the products from catalytic crackers and hydroformers, which are analyzed for C_1 through C_5 hydrocarbons, fixed gases, and hydrogen. Although a complete isomer breakdown is not made, sufficient information is obtained to satisfy most requirements. This has been a particularly useful measurement in the case of hydroformate make-gases where the sample may contain as much as 95% hydrogen. It is possible to determine some 19 other components in the remaining 5% of the sample.

Mass spectrometry is also used for the analysis of petroleum liquids. Light (C_5 – 121 °C) naphthas can be analyzed for individual paraffins, naphthenes, and aromatics. Samples boiling in the gasoline range can be analyzed for total paraffins, total noncondensed naphthenes, condensed naphthenes (2, 3, 4, etc. rings) and for C_6, C_7, C_8, C_9, C_{10} benzenes and naphthalenes. Heating oils and lube oils can be analyzed for both aromatics and saturates. The aromatics determined are 2, 3, 4, etc. ring-type as well as the same ring-type thiophenes. The saturates determined are the total paraffins, noncondensed naphthenes, and condensed naphthenes (2, 3, 4, etc. rings). Many of these samples, of course, may be solid at room temperature. Other solid samples analyzable by mass spectrometry include refined waxes, which are analyzed for normal paraffins, isoparaffins and naphthenes.

Mass spectrometry is very useful in qualitative analysis. Instrumentation for this includes high-resolution spectrometers and combination units consisting of a gas chromatograph linked to a mass spectrometer.

Mass spectrometers are commercially available with resolutions of one part in 50 000 and greater. With these instruments it is possible to examine high-boiling fractions for specific compound types, and in conjunction with low-voltage mass spectrometry, they have been used very successfully for the identification of oxygen-, sulfur- and nitrogen-containing compound. High-resolution mass spectrometry is also extremely useful for obtaining structural information on relatively pure compounds.

The direct coupling of a gas chromatograph to a mass spectroscopy (GC/MS) has resulted in an extremely powerful tool for the characterization of complex mixtures. Individual peaks in a chromatogram can usually be identified by their mass spectrum. GC/MS has been used in the identification of contaminants in feedstreams at the parts per million level, for the complete characterization of naphthas which can have over 250 peaks in their gas chromatograms, and for determining isomer distribution in products from experimental isomerization or reforming reactors.

A technique called nitric oxide ionization spectrometry evaluation (NOISE, though it really is more of a modification to the standard GC/MS methods) has gained some popularity in the 1990s for petroleum distillates in the range of 250–1000 °F (120–540 °C). In the NOISE method, bp fractions are bombarded with NO^+ ions. A mass spectrometer is used to identify the individual components and reports them by carbon number as well

as by hydrogen deficiency. Knowing these two quantities for all detected components mathematically allows for a PIANO and sulfur analysis of the sample at hand. A drawback of this method is its relatively poor accuracy when applied to C_6 and C_7 hydrocarbons, so that this lighter naphtha has to be removed (easily done by several methods but GC is usually the most readily made automatic) first. It is also helpful to break down a full range cut into several subcuts for separate sequential analysis to improve the accuracy.

Here are some additional standards that may be applicable in the use of mass spectrometry analysis of regulated fuel components:

- ASTM D-1658 – Carbon Number Distribution of Aromatic Compounds in Naphthas by Mass Spectrometry, Standard Practice
- ASTM D-2498 – Isomer Distribution of Straight-chain Detergent Alkylate By Mass Spectrometry, Standard Practice
- ASTM D-2567 – Molecular Distribution Analysis for Monoalkylbenzenes by Mass Spectrometry, Standard Method
- ASTM D-2789 – Hydrocarbon Types in Low Olefinic Gasoline By Mass Spectrometry, Standard Test Method
- ASTM-E899 – Records Management in Mass Spectrometry Laboratories Performing Analysis in Support of
- US EPA-Method-8240B – Volatile Organics by Gas Chromatography/Mass Spectrometry–packed Column Techniques
- US EPA-Method-8270B – Semivolatile Organic Compounds by Gas Chromatography/Mass Spectrometry–capillary
- Patent-5461235 – Mass Spectrometry Apparatus and Method Relating Theretofore
- Patent-5481108 – Method for Ion Detection and Mass Spectrometry and Apparatus Thereof
- ASTM D-2425 – Hydrocarbon Types in Middle Distillates by Mass Spectrometry, Standard Test Method for
- ASTM D-2650 – Chemical Composition of Gases by Mass Spectrometry, Standard Test Method for

6.5 Volatility Measurements

Volatility is a primary factor in liquid fuel quality. The vaporizing tendencies of all types of fuels are important to their combustion characteristics and general utilization. Volatility is also of considerable significance to the quality of other liquid petroleum products, for example, solvents and lubricants.

For some purposes it is necessary to have information on the initial stage of vaporization. To supply this information, flash fire, vapor pressure, and evaporation tests are available. The data from the early stages of the several distillation tests are useful also. In some applications it is important to know the tendency of a product to vaporize partially or completely at ambient temperatures.

6.5.1 Flash and Fire

The *flash point* of a petroleum product is the temperature to which the product must be heated under the prescribed conditions of the test to give sufficient vapor to form a mixture with air that can be ignited by a suitable flame. The *fire point* is the temperature at which the oil's vapor ignites and continues to burn for 5 s. If the flash point is known there is additional value in knowing its fire point. The importance of flash point data has led to the development of standardized procedures, including ASTM D-56, D-92, and D-93.

Petroleum products vary widely in flash and fire points. Gasolines flash well below freezing. Solvents, have flash points ranging from below 21 °C (70 °F) up to 52 °C (125 °F). Kerosines flash at 38 °C (100 °F) to 66 °C (150 °F), while heavier fuel oils flash from 66 °C to 121 °C (250 °F). Lubricating oils have flash points from 275 to 700 °F (135–370 °C). Fire points range from 5.5 °C (10 °F) to 22 °C (70 °F) higher than the flash points, with the greater spread appearing in the heavier products. When the flash point is given, the method used in determining it should be mentioned.

The Cleveland open-cup (ASTM D-92) method, the one almost universally used, employs a brass cup supported by a metal ring, see Figure 12. A flame or electric heater under the cup heats the oil sample, in which the bulb of a thermometer is immersed. A tiny pilot flame is moved over the surface of the heated oil at every 5 °F (2.8 °C) rise in temperature. When the vapor above the oil flashes, the temperature reading indicates the flash point of the oil. Theoretically, it is possible to test the whole range of petroleum products with a single flash test. In actual practice it has been better to use three instruments because flash points of petroleum products vary over a wide range. The tag closed tester (ASTM D-56) is used to test all mobile liquids that flash below 79 °C, but not for products classed as fuel oil. The Pensky–Martens closed tester (ASTM D-93) is used to test diesel and heating fuel oil unless other methods are specified. The open cup tester (ASTM D-92) is used for determining both flash and fire point for all petroleum products except fuel oil and those which have a flash point below 79 °C (175 °F).

Flash points are most generally used to determine fire and explosion hazards. For products with flash points below 33 °C (90 °F), special precautions are necessary for

Figure 12 Cleveland open cup tester.

safe handling. Products having flash points in the 33 °C to 66 °C range may also present problems with respect to safe handling and storage. Products with flash points above 66 °C are relatively safe to handle and, in this case, flash points are generally determined as indirect measures of some other quality. For example, flash point is often used by manufacturers and marketers of petroleum products to detect contamination or as an aid in identifying a particular petroleum product.

6.5.2 Reid Vapor Pressure

6.5.2.1 Bomb Methods The RVP[31,55–58,75] apparatus consists essentially of a double-chambered bomb. The upper chamber is fitted with a pressure gage and contains atmospheric air. The lower chamber which has 0.25 the capacity of the upper chamber is filled with a sample of the liquid to be tested. Both the sample and its chamber are first chilled to reduce premature evaporation. The bomb is then sealed, care being take to prevent the introduction of abnormal pressures.

The sealed bomb is immersed in a 38 °C (100 °F) bath. To assure a maximum opportunity for evaporation, the bomb is removed from the path periodically for brief but vigorous shaking. During this process, a small portion of each fraction is vaporized, the amount depending upon its vapor pressure at test temperature and its concentration in the sample. When an equilibrium is reached, that is, when two consecutive gage readings are identical, that gage reading is recorded as the ''uncorrected vapor pressure''.

The bomb pressure consists of the atmospheric pressure plus the sum of the individual vapor pressures of the fractions, each modified according to the ratio of its liquid volume to the total liquid volume. Obviously, this pressure is greater than atmospheric but since the gage registers only pressures above atmospheric, its reading is related only to vapor pressure.

The gage is removed from the bomb, calibrated against a mercury manometer at the value of the uncorrected vapor pressure and any discrepancy noted. The uncorrected value is then corrected for both the gage calibration and the change in the pressure of the water vapor and air in the air chamber between the initial air temperature and 38 °C.

The discussion above is the traditional D-323 method of analysis. Since the water vapor pressure in the vapor over oxygenated fuels is affected by the presence of that oxygenate, D-4953 has its own set of corrections to be made to the ''uncorrected cell vapor pressure''.

6.5.2.2 Minicell Methods Since the bomb methods are slow and time consuming, several alternate methods and equipment have been developed to determine vapor pressure of gasoline samples. These were developed with ease of in-field certification in mind.

Portable Cell Test Apparatus. The type of apparatus suitable for use in this test method employs a small volume test chamber incorporating a transducer for pressure measurements and associated equipment for thermostatically controlling the chamber temperature and for evacuating the test chamber prior to sample introduction. It is often generically called a Grabner cell apparatus after one of the first and most prominent vendors of such portable test equipment. Several other vendors have good equipment on the market as well, but the naming sticks, much as Xerox and Coke, describe a wide class of photostatic copiers or cola drinks.

The test chamber contains between 5 and 50-mL of liquid and is capable of containing a vapor-to-liquid ratio of 1.0 up to 4.0 (minimum by standard). A known volume of chilled air-saturated sample is introduced into the evacuated thermostatically controlled test chamber. The internal volume of the test chamber is five times that of the total test specimen introduced into the chamber. After injection into the test chamber, the test specimen is allowed to reach thermal equilibrium at the test temperature, 37.8 °C (100 °F). The resulting rise in pressure in the chamber is measured using a pressure transducer sensor and indicator. Only total pressure

measurements (sum of the partial pressure of the sample and the partial pressure of the dissolved air) are used in this test method, although some instruments can measure the absolute pressure of the sample as well.

The measured total vapor pressure is converted to a dry vapor pressure equivalent (DVPE) by use of a correlation equation. A correction to this value is necessary to account for the biases between the cell pressure and that which would be measured by standard D-4953 laboratory testing. The 1991 ASTM D-2.02 Round Robin test report mentions several correcting equations.

Automatic Cell Test Method. The chilled sample cup of the automatic vapor pressure instrument is filled with chilled sample and is coupled to the instrument inlet fitting. The sample is then automatically forced from the sample chamber to the expansion chamber where it is held until thermal equilibrium at 37.8 °C (100 °F) is reached. In this process the sample is expanded to five times its volume (4 : 1 vapor-to-liquid ratio). The vapor pressure is measured by a pressure transducer.

The measured vapor pressure is automatically converted to a DVPE value by the instrument. A correction to this value is necessary to account for the observed bias between the test result and that obtained by Test Method D 4953.

The instrument automatically calculates the DVPE from the measured total pressure by means of the following correction equation to correct for the relative bias, found in the 1991 ASTM D-202 Round Robin test program, between the results obtained by this test method and the dry vapor pressure values measured in accordance with Test Method D 4953 as follows, Equation (5):

$$\text{DVPE (kPa)} = (0.941\,X) + 3.22 \quad \text{or}$$
$$\text{DVPE (psi)} = (0.941\,X) + 0.467 \qquad (5)$$

where X is the measured total pressure in kilopascals (pounds-force per square inch).

7 APPLICABLE REGULATORY MEASUREMENT STANDARDS BY CRITERIA COMPONENT[41,47]

7.1 Introduction

This section presents a more detailed listing and discussion of several of the more commonly recognized standards for analysis of fuels constituents for environmental regulatory reasons. It covers the major standards for North America and the EU, as these areas are furthest advanced in environmental concerns. US EPA and EU regulatory standards are the foundation for environmental regulations in much of the rest of the world, even if enforcement in some of these areas lags behind the developed world.

The standards mentioned in this section are not repeated verbatim. The reader can easily obtain these directly and inexpensively, as needed, from either ASTM or ANSI/ISO. In fact, since these standards are routinely updated by several diligent industrial and government committee representatives, any detailed coverage discussed here is likely to be obsolete within a few years.

The content of these standards varies greatly. In some cases, procedures for using specific analytical equipment are provided in great detail, along with illustrations and lots of minutiae. In other cases, they only detail the allowable limits and provide an official ''accuracy'' statement of a given type of analytical procedure for a specific type of measurement on a certain type of fuel product stream. Statistical reliability metrics, calibration standards, and sample preparation methods are three of the most common areas of coverage that these methods provide.

Analytical instrument vendors typically provide ''off the shelf'' systems that are calibrated and verified to one or more of several appropriate standards and analytical environments. ISO 9000 and ISO 14000 requirements for commercial and environmental compliance equipment are fairly strict in removing human error as much as possible from the sampling and measurement process. An IR spectroscopy-based standard may provide a one way of interpreting a spectral chart for a certain composition of sample material and another for a different type of sample. Modern analyzers not only take the spectra, but also calculate the necessary information from digital analysis of the spectral pattern. (The days of doing graphical integration of peak charts by hand – literally counting chart crosshatching scale squares – are over.) To change from one standard methodology to another is often now a matter of choosing a different methodology on a Microsoft Windows™-based computer interface dialog box and hitting the return key on a keyboard. ISO 9000 manufacturing compliance also sets some fairly strong legal requirements for calibration of a piece of test equipment to prevailing standards.

The typical standard values stated in the SI (Système International d'Unitès) units are to be regarded as the standard conversion. Conversion to and from these units to English-language engineering values may or may not be covered. A few of the standards even specify the precision with which such conversions should be reported! In most cases, normal prevailing laboratory practices for accuracy and precision of reported numbers are more than adequate to maintain adherence to the standard. If in doubt, there are even standards for laboratory practice standards that can be consulted.

None of the standards address any safety issues, if any, associated with its use. It is the responsibility of the user of the standard to establish appropriate safety and health practices and determine the applicability of regulatory limitations prior to use.

7.2 Choosing the Appropriate Standards

With the availability of several perfectly valid alternatives for obtaining chemical analyses, how should one determine which one(s) to use. This may be as simple an answer as referring to the local regulatory agencies' codified requirements. Usually, they present alternatives as well. In some cases, multiple regulatory governing bodies have conflicting specifications.

Table 13 lists the adopted and equivalent test methods for the CARB components whose designated test methods have recently been amended. It should be noted that certain conditions must be met when using the equivalent test methods for aromatic hydrocarbons (aromatics) and low level (1–10 ppm) sulfur.

In fact, each refiner is free to control and do analysis by whatever method they feel comfortable with. Whatever is measured and however the numbers are obtained, they must provide answers compatible with whatever the local governing agencies (all of them) have deemed as the standard of choice.

7.3 Distillation Methodology

7.3.1 D86 Distillation of Petroleum Products

This test method covers the distillation of natural gasolines, motor gasolines, aviation gasolines, aviation turbine fuels, special boiling point spirits, naphthas, white spirit, kerosines, gas oils, distillate fuel oils, and similar petroleum products, utilizing either manual or automated equipment. It is the most widely used distillation standard for naphtha-containing fuels. There is some question about its accuracy with diesel range petroleum fractions but most distillations of this material are reported as D86 or its equivalent from a related test.

7.3.2 D3710 Boiling Range Distribution of Gasoline and Gasoline Fractions by Gas Chromatography

This test method covers the determination of the boiling range distribution of gasoline and gasoline components. This test method is applicable to petroleum products and fractions with a FBP of 500 °F (260 °C) or lower as measured by this test method. D3710 is designed to measure the entire boiling range of gasoline and gasoline components with either high or low RVP and is commonly referred to as GC distillation. It is essentially a GC-equivalent procedure to obtain D86 assay information. D-3710 has not been validated for gasolines containing oxygenated compounds (for example, alcohols or ethers).

7.3.3 D1160 Distillation of Petroleum Products at Reduced Pressure

This test method covers the determination, at reduced pressures, of the range of boiling points for petroleum products that can be partially or completely vaporized at a maximum liquid temperature of 400 °C. Both a manual method and an automatic method are specified. It is not really suitable for gasoline or kerosine but may be for heavier diesel stocks. It is also not amenable to on-line

Table 13 Criteria fuel component measurement standards

Component	CARB adopted method	CARB equivalent method	US EPA method	ACEA standards
Oxygen	ASTM D-4815	Prop. GC/FTIR[a]		
Olefins	ASTM D-1319a	ASTM D-1159	ASTM D-1319a	ISO 3837
Benzene	ASTM D-5580	Prop. GC/FTIR[a]	ASTM D-3606	EN-238
Aromatics (gasoline)	ASTM D-5580-95	Prop. GC/FTIR w/corr for ASTM D-5580	ASTM D-1319	
RVP	ASTM D-4953-	ASTM D-5191 w/corr. for ASTM D-4953	ASTM D-4953	ISO 3007-1996
T50, T90, FBP[b]	ASTM D-86-95	ASTM D-86	ASTM D-86	ISO 3405-1988
Sulfur				
1–10 ppm	ASTM D-5453	ASTM D-4045 (modified)		
10 ppm+	ASTM D-2622 (modified)	ASTM D-5453		
Phosphorus	ASTM D-3231	ASTM D-3231	ASTM D-3231	
Lead	ASTM D-4059			EN 237

[a] "Proposed ASTM Standard Test Method for Determination of Oxygenates, Benzene, Toluene, C_8–C_{12} Aromatics and Total Aromatics in Finished Gasoline by GC/FTIR."
ACEA, Association des Constructeurs Européens de l'Automobile.
[b] FBP.

analysis as it is clumsy to perform, though it is simpler than TBP (true boiling point). D1160 values can be reasonably converted to TBP and thence to equivalent D86 values via the *API Technical Databook*.[75]

7.3.4 D2887-e1 Boiling Range Distribution of Petroleum Fractions by Gas Chromatography

This test method covers the determination of the boiling range distribution of petroleum products. D2887 is applicable to petroleum products and fractions having a FBP of 538 °C (1000 °F) or lower at atmospheric pressure as measured by this test method. It is limited to samples having a boiling range greater than 55 °C (176 °F), and having a vapor pressure sufficiently low to permit sampling at ambient temperature. It is not to be used for the analysis of gasoline samples or gasoline components, which should be analyzed by Test Method D3710.

7.3.5 D2892 Distillation of Crude Petroleum (15-Theoretical Plate Column)
